After this process the density of the more quickly diffusing gas was reduced to 2.02, while that of the less quickly diffusing had increased to 2.27. The light portion on rediffusion hardly altered in density, while the heavier portion, when divided into three portions by diffusion, showed a considerable difference in density between the first third and the last third. A similar set of operations was carried out with a fresh quantity of helium, in order to accumulate enough gas to obtain a sufficient quantity for a second series of diffusions. The more quickly diffusing portions of both gases were mixed and re-diffused. The density of the lightest portion of these gases was 1.98, and after other 15 diffusions the density of the lightest portion had not decreased. The end had been reached; it was not possible to obtain a lighter portion by diffusion. The density of the main body of this gas is therefore 1.98; and its refractivity, air being taken as unity, is 0.1245. The spectrum of this portion does not differ in any respect from the usual spectrum or helium.

As re-diffusion does not alter the density or the refractivity of this gas, it is right to suppose that either one definite element has now been isolated or that if there are more elements than one present they possess the same, or very nearly the same, density and refractivity. There may be a group of elements, say three, like iron, cobalt and nickel; but there is no proof that this idea is correct and the simplicity of the spectrum would be an argument against such a supposition. This substance, forming by far the larger part of the whole of the gas, must, in the present state of our knowledge, be regarded as pure helium.

On the other hand, the heavier residue is easily altered in density by re-diffusion, and this would imply that it consists of a

small quantity of a heavy gas mixed with a large quantity of the light gas. Repeated re-diffusion convinced us that there was only a very small amount of the heavy gas present in the mixture. The portion which contained the largest amount of heavy gas was found to have the density 2.275, and its refractive index was found to be 0.1333. On re-diffusing this portion of gas until only a trace sufficient to fill a Plücker's tube was left, and then examining the spectrum, no unknown lines could be detected, but, on interposing a jar and spark gap, the well-known blue lines of argon became visible; and even without the jar the red lines of argon and the two green groups were distinctly visible. The amount of argon present, calculated from the density, was 1.64 per cent., and from the refractivity 1.14 per cent. The conclusion had therefore to be drawn that the heavy constituent of helium, as it comes off the minerals containing it, is nothing new, but, so far as can be made out, merely a small amount of argon.

If, then, there is a new gas in what is generally termed helium, it is mixed with argon, and it must be present in extremely minute traces. As neither helium nor argon has been induced to form compounds, there does not appear to be any method, other than diffusion, for isolating such a gas, if it exists, and that method has failed in our hands to give any evidence of the existence of such a gas. It by no means follows that the gas does not exist; the only conclusion to be drawn is that we have not yet stumbled on the material which contains it. In fact, the haystack is too large and the needle too inconspicuous. Reference to the periodic table will show that between the elements aluminium and indium there occurs gallium, a substance occurring only in the minutest amount on the earth's surface; and following silicon, and preceding tin, appears the element germanium, a body which has as yet been recognized only in one of the rarest of minerals, argyrodite. Now, the amount of helium in fergusonite, one of the minerals which yields it in reasonable quantity, is only 33 parts by weight to 100,000 of the mineral; and it is not improbable that some other mineral may contain the new gas in even more minute proportion. If, however, it is accompanied in its still undiscovered source by argon and helium, it will be a work of extreme difficulty to effect a separation from these gases.

In these remarks it has been assumed that the new gas will resemble argon and helium in being indifferent to the action of reagents, and in not forming compounds. This supposition is worth examining. In considering it the analogy with other elements is all that we have to guide us.

We have already paid some attention to several triads of elements. We have seen that the differences in atomic weights between the elements fluorine and manganese, oxygen and chromium, nitrogen and vanadium, carbon and titanium, is in each case approximately the same as that between helium and argon, viz., 36. If elements further back in the periodic table be examined, it is to be noticed that the differences grow less, the smaller the atomic weights. Thus, between boron and scandium, the difference is 33; between beryllium (glucinum) and calcium, 31; and between lithium and potassium, 32. At the same time, we may remark that the elements grow liker each other the lower the atomic weights. Now helium and argon are very like each other in physical properties. It may be fairly concluded, I think, that in so far they justify their position. Moreover, the pair of elements which show the smallest difference between their atomic weights is beryllium and calcium; there is somewhat greater difference between lithium and potassium. And it is in accordance

with this fragment of regularity that helium and argon show a greater difference. Then, again, sodium, the middle element of the lithium triad, is very similar in properties both to lithium and potassium; and we might, therefore, expect that the unknown element of the helium series should closely resemble both helium and argon.

Leaving now the consideration of the new element, let us turn our attention to the more general question of the atomic weight of argon, and its anomalous position in the periodic scheme of the elements. The apparent difficulty is this: The atomic weight of argon is 40; it has no power to form compounds, and thus possesses no valency; it must follow chlorine in the periodic table, and precede potassium; but its atomic weight is greater than that of potassium, whereas it is generally contended that the elements should follow each other in the order of their atomic weights. If this contention is correct, argon should have an atomic weight smaller than 40.

Let us examine this contention. Taking the first row of elements, we have:

Li = 7, Be = 9.8, B = 11, C = 12, N = 14, O = 16, F = 19, ? = 20.

The differences are:

2.8, 1.2, 1.0, 2.0, 2.0, 3.0, 1.0.

It is obvious that they are irregular. The next row shows similar irregularities. Thus:

(? = 20), Na = 23, Mg = 24.3, Al = 27, Si = 28, P = 31, S = 32, Cl = 35.5, A = 40.

And the differences:

3.0, 1.3, 2.7, 1.0, 3.0, 1.0, 3.5, 4.5.

The same irregularity might be illustrated by a consideration of each succeeding row. Between argon and the next in order, potassium, there is a difference of —0.9; that is to say, argon has a higher atomic weight than potassium by 0.9 unit; whereas it might be expected to have a lower one, seeing that potassium follows argon in the table. Farther on in the table there is a similar discrepancy. The row is as follows:

Ag = 108, Cd = 112, In = 114, Sn = 119, Sb = 120.5, Te = 127.7, I = 127.

The differences are:

4.0, 2.0, 5.0, 1.5, 7.2, —0.7.

Here, again, there is a negative difference between tellurium and iodine. And this apparent discrepancy has lead to many and careful redeterminations of the atomic weight of tellurium. Professor Brauner, indeed, has submitted tellurium to methodical fractionation, with no positive results. All the recent determinations of its atomic weight give practically the same number, 127.7.

Again, there have been almost innumerable attempts to reduce the differences between the atomic weights to regularity, by contriving some formula which will express the numbers which represent the atomic weights, with all their irregularities. Needless to say, such attempts have in no case been successful. Apparent success is always attained at the expense of accuracy, and the numbers reproduced are not those accepted as the true atomic weights. Such attempts, in my opinion, are futile. Still, the human mind does not rest contented in merely chronicling such an irregularity; it strives to understand why such an irregularity should exist. And, in connection with this, there are two matters which call for our consideration. These are: Does some circumstance modify these 'combining proportions' which we term 'atomic weights'? And is there any reason to suppose that we can modify them at our will? Are they true 'constants of Nature' unchangeable, and once for all determined? Or are they constant merely so long as other circumstances, a change in which would modify them, remain unchanged.

In order to understand the real scope of

such questions, it is necessary to consider the relation of the 'atomic weights' to other magnitudes, and especially to the important quantity termed 'energy.'

It is known that energy manifests itself under different forms and that one form of energy is quantitatively convertible into another form, without loss. It is also known that each form of energy is expressible as the product of two factors, one of which has been termed the 'intensity factor,' and the other the 'capacity factor.' Professor Ostwald, in the last edition of his 'Allgemeine Chemie,' classifies some of these forms of energy as follows:

Kinetic energy is the product of Mass into the square of velocity.

Linear energy is the product of Length into force.

Surface energy is the product of Surface into surface tension.

Volume energy is the product of Volume into pressure.

Heat energy is the product of Heat-capacity (entropy) into temperature.

Electrical energy is the product of Electric capacity into potential.

Chemical energy is the product of 'Atomic weight' into affinity.

In each statement of factors, the 'capacity factor' is placed first, and the 'intensity-factor' second.

In considering the 'capacity factors,' it is noticeable that they may be divided into two classes. The two first kinds of energy, kinetic and linear, are *independent of the nature of the material* which is subject to the energy. A mass of lead offers as much resistance to a given force, or, in other words, possesses as great inertia as an equal mass of hydrogen. A mass of iridium, the densest solid, counterbalances an equal mass of lithium, the lightest known solid. On the other hand, surface energy deals with molecules, and not with masses. So does volume energy. The volume energy of two grammes of hydrogen, contained in a vessel of one litre capacity, is equal to that of thirty-two grammes of oxygen at the same temperature and contained in a vessel of equal size. Equal masses of tin and lead have not equal capacity for heat; but 119 grammes of tin has the same capacity as 207 grammes of lead, that is, equal atomic masses have the same heat capacity. The quantity of electricity conveyed through an electrolyte under equal difference of potential is proportional, not to the mass of the dissolved body, but to its equivalent, that is, to some simple fraction of its atomic weight. And the capacity factor of chemical energy is the atomic weight of the substance subjected to the energy. We see, therefore, that while mass or inertia are important adjuncts of kinetic and linear energies all other kinds of energy are connected with atomic weights, either directly or indirectly.

Such considerations draw attention to the fact that quantity of matter (assuming that there exists such a carrier of properties as we term 'matter'.) need not necessarily be measured by its inertia, or by gravitational attraction. In fact, the word 'mass' has two totally distinct significations. Because we adopt the convention to measure quantity of matter by its mass, the word 'mass' has come to denote 'quantity of matter.' But it is open to anyone to measure a quantity of matter by any other of its energy factors. I may, if I choose, state that those quantities of matter which possess equal capacities for heat are equal, or that 'equal numbers of atoms' represent equal quantities of matter. Indeed, we regard the value of material as due rather to what it can do than to its mass; and we buy food, in the main, on an atomic, or, perhaps, a molecular basis, according to its content of albumen. And most articles depend for their value on the amount of food required by the producer or the manufacturer.

The various forms of energy may, there-

fore, be classified as those which can be referred to an 'atomic' factor, and those which possess a 'mass' factor. The former are in the majority. And the periodic law is the bridge between them; as yet, an imperfect connection. For the atomic factors, arranged in the order of their masses, display only a partial regularity. It is undoubtedly one of the main problems of physics and chemistry to solve this mystery. What the solution will be is beyond my power of prophecy; whether it is to be found in the influence of some circumstance on the atomic weights, hitherto regarded as among the most certain 'constants of Nature,' or whether it will turn out that mass and gravitational attraction are influenced by temperature, or by electrical charge, I cannot tell. But that some means will ultimately be found of reconciling these apparent discrepancies, I firmly believe. Such a reconciliation is necessary, whatever view be taken of the nature of the universe and of its mode of action; whatever units we may choose to regard as fundamental among those which lie at our disposal.

In this address I have endeavored to fulfill my promise to combine a little history, a little actuality and a little prophecy. The history belongs to the Old World; I have endeavored to share passing events with the New; and I will ask you to join with me in the hope that much of the prophecy may meet with its fulfilment on this side of the ocean.

William Ramsay.

ADDRESS BY THE PRESIDENT BEFORE THE SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION.

In opening the proceedings of this fourth annual meeting of the Society for the Promotion of Engineering Education I wish, first of all, to congratulate the Society upon its great success thus far in accomplishing the object for which it was founded, an object fully expressed in its name. The volumes of its proceedings already published are filled with discussions and the ripe conclusions of the best thought that can be expressed to-day upon many phases of engineering education. No one who desires to become informed upon these matters can afford to neglect these volumes. It is believed that all interested in the object of our Society will find it to their advantage to unite with us.

One striking peculiarity of engineering education seems to me to lie in the fact that it has been determined so largely as to its scope and the lines of its development by the engineering colleges themselves in advance of the formulated demands of the engineering profession and of the public in general, and often, indeed, in opposition to such demands. Through the wisdom and foresight of these organizers of engineering education the profession of engineering has come forth during this generation into public estimation as a learned and responsible profession, quite the peer of law or medicine. This is the work of the engineering colleges, and from the deliberations of this Society it is evident that they still have a large work before them. The educational institutions of our country are in a state of flux. The present movement in education is powerful. These times will be looked back to in future days as those in which mighty educational forces were inaugurated and were adapted to the needs of the nation just as it was coming to its full consciousness as one of the great family of nations, a consciousness of power and responsibility that is causing it to depart somewhat from the revered advice of Washington, which was to keep aloof from European affairs and entanglements with other nations of the earth and work out its own destiny by itself. National growth and our multiplied facilities for communication have greatly modi-

fied our feeling as to this. The triumphs of the engineer in applying steam and electricity are making of one blood all nations of the earth. But the one thing that is making and will make of us a nation worthy of our heritage is our educational life. Our republican institutions, the pride of our early national life, cannot continue such except for the reinforcement and help to come from the enlarged scope of education to-day.

It has seemed to me that I could not, perhaps, use the short time allotted to me for this address better than in trying to summarize some of the thoughts which have appeared in the papers and discussions before this Society, which had its beginning in the Engineering Congress of the Columbian Exposition at Chicago. What I have to say is called forth by the enlarged responsibilities and new conception of the professional position of the engineer of to-day, and the course of study necessary to fit him for the responsibilities of his position.

And, first of all, I think I am right in saying that the demand is growing stronger that courses of engineering instruction shall include nothing else, that is, that they shall be as completely professional in their character as are professional courses in law and medicine.

This demand is not made by the general public, nor to any great extent, I think, by practicioners in the engineering profession. These are greatly impressed with the necessity the engineer has for general culture, and rightly so. The demand is one made by the engineering colleges themselves. At present the curriculum of our average engineering college includes from 20 to 25 per cent. of culture studies, such as English, French and German; from 30 to 25 per cent. of indirectly technical study, as Mathematics, Physics, etc.; and 50 per cent. of directly technical study.

The culture studies are of fundamental importance to the engineer. He usually obtains far too small an amount of such study before graduation. He finds himself poorly fitted in this respect for his subsequent career. His preparation in the use of language for writing and speaking has been too meager. He finds that his professional work is not of a character to supplement his education in this particular. Yet culture studies are out of place in any engineering course with strongly marked technical tendencies. Both student and instructor feel this. The two kinds of study interfere with each other. The student cannot fix his attention on culture study while absorbed in the beginnings of technical study. The instructor in the culture studies feels the hopelessness of the task and must perforce be content with a lifeless, memoriter fulfilment of task work. The instructors in the technical studies are apt to be impatient at the time and attention demanded by the culture studies as more or less of an obstacle and hindrance to what is rightly regarded as the student's main work.

Under such circumstances as these it seems clear that the culture studies must soon disappear from our engineering courses. This change will, doubtless, come about gradually and will occur in the more fully developed courses first. It will not mean that culture studies shall be omitted from the education of the engineer. It will simply mean that he must obtain them outside of the engineering course, preferably before he enters it. The tendency, on every hand, is to insist more strongly than heretofore upon the culture studies as essential to the engineer. To insure large success he must be a man of broad culture. He is to direct large enterprises as well as plan the necessary structure and machinery of the plant, and that man will succeed who by the influence of his personality, with

tongue and pen, shows himself able to hold his position as the peer of other great organizers of our industrial life. The highest success is to be quickly reached as a rule only by those engineers who have had adequate preliminary education in culture studies, which is another name for the liberal arts. Such culture is now most readily and suitably attained by pursuing some part, more or less complete, of a regular college course. This will come to be regarded more and more as the best preparation for a professional course in engineering, as it is now for a professional course in law and medicine.

Following the consideration of the culture studies comes that of the indirectly technical studies, such as mathematics, mechanics, physics, chemistry and drawing, which at the present time occupy between one-third and one-fourth of the time of the average engineering course. These studies rightfully have place in the course, but the question whether the amount and quality of the work at present accomplished is entirely satisfactory is one which has been much debated. It may be said fairly, I think, that the standard of work in mathematics, mechanics and physics has been gradually but surely advancing in all the engineering colleges, against the opposition of a large part of those engaged in engineering practice, who have been largely opposed to teaching more mathematics, etc., than they themselves were taught, saying that they have had no use for much of that which was taught them. This argument has seemed perfectly conclusive to those who have advanced it, and also to the student, who naturally finds such studies hard, and (as he thinks) much in the way of his rapidly advancing to purely technical study. This view has also often met acceptance with the technical professors, who are largely in sympathy with those engaged in practice. But the argument is fallacious, as I am convinced. The contrary view has prevailed in the papers before this Society. We are to look upon this gradual advance of the standard in mathematics, etc., as a movement which has not as yet ceased, but one still in progress.

Perhaps the point of greatest difficulty, so far as mathematics is concerned, has been to have the differential and integral calculus so incorporated into the engineering courses as to really become part of the working equipment of the student. That may not have been completely accomplished as yet, but that is the standard now regarded as essential, and one which is more and more nearly attained year by year. It is my opinion that it will not be satisfactorily reached until the course in calculus includes the treatment of differential equations. This conclusion is forced upon me, not merely by the abstract consideration that physical and mechanical questions find their expression best by the use of differential equations; but the problems arising just now in the theory of alternating currents must evidently be treated on the basis of their differential equations. Heretofore it has been possible to satisfy the student as to the treatment and solution of the mechanical and physical problems in his course without special study of differential equations, though he was likely to meet a number of points that were puzzling and unsatisfactory by reason of his ignorance of that subject. But now the matter can no longer be avoided, I think, as no other treatment can give the necessary insight into the complicated phenomena which must be fully mastered to-day by the student in electricity.

Mechanics, too, and physics have taken on a larger and larger significance. The principles of mechanics underlie all physical phenomena and all engineering processes. Their formal study has been found to be of increasing importance in under-

standing the strength and resistance of materials, the thermodynamics of steam- and gas-engines, turbines, electrical generators, motors and transformers.

As to physics and chemistry it is unnecessary for me to explain how small are the opportunities compared with what is desirable. The state of knowledge in these sciences is steadily advancing. Hertz waves and Röntgen rays are meeting technical applications, and new knowledge must have place. The field constantly increases. More time must be taken for such subjects. We cannot escape it. It seems impracticable to secure it by having more physics and chemistry taught in the preparatory schools. Such work is not satisfactory. It is preferable to relegate more of the pure mathematics to those schools.

We are to look in the future, as I think, for an increase in the amount and an improvement in the quality of the work in all that part of the work in our engineering courses, which, though but indirectly technical, affords the theoretical basis of the strictly technical studies of the course.

The improvement in the quality of the instruction will lie, for one thing, along the line of the illustrations and problems employed, in seeing to it that they have to do with things tangible and in the direction of practice. This will help secure the necessary interest in theory and make it, as it should be, the basis of practice.

We now come to the consideration of those studies which are strictly and directly technical. They occupy in most engineering courses at least one half of the course. The improvements which have taken place in engineering courses have occurred more largely in this part of the work than elsewhere, but great divergence of opinion has naturally arisen as to what is best. In certain courses of mechanical engineering an excessive amount of manual training and shop work was at first introduced; inexpert opinion still lays undue emphasis upon this part of the course in mechanical and electrical engineering. But as the true function of manual training and trades schools comes to be better understood, and their value to the community in developing handicraft and in furnishing education to the artisan as distinguished from the professional engineer, not only will such schools be well supported and greatly increased in number, but they will be sharply distinguished in the minds of all from the engineering colleges. These last are not intended to make skilled workmen, though some seem still to think so. The engineering student needs a comparatively small amount of practice in wood working, which shall be especially directed toward pattern making; a short experience in the blacksmith shop and foundry, and somewhat more of metal working by hand and machine tools, together with the management of boilers and steam engines. But any effort to make prolonged exercises in these subjects take the place of more theoretical study in an endeavor to make a workman or a foreman instead of an engineer.

The same is true of extended civil engineering field practice with instruments. It is quite possible to put too great emphasis upon it and consume more time with it than the study warrants. The temptation to do that is strong. It must be remembered, however, that surveying is not today the principal occupation of most engineers. The plan of putting shop practice, field work and other like practical parts of the course into the long vacations has much in its favor and seems to be coming more into vogue. The student should graduate from the shop and the surveying corps as soon as he has obtained a moderately good acquaintance with tools and processes and enter the testing laboratory. That is the true field for extended practical work in

the engineering course. In it the work should be arranged with regular sets of graded exercises covering the measurement, proper records and working out the results of tests on all the materials and processes treated in the theoretical work of the student as well as whatever he is likely to encounter in practice or inspection. It is only by prolonged drill in testing that he can acquire the necessary basis for that professional and practical judgment which will make his opinion of value. While thus insisting on testing laboratories as the best and most important recent development of our engineering colleges as well as one of the most costly parts of them, it is needful to insist at the same time and with still greater emphasis on the paramount importance of the theoretic instruction in the mathematical, mechanical and scientific principles which should furnish the core of every engineering course. This it is which engineering colleges must teach and trades schools may entirely omit. Engineering colleges may leave out shops and laboratories, and some do so; they may omit culture studies, and have very imperfect instruction in drawing and design, without forfeiting the claim to give engineering courses of considerable value; but no engineering college can afford, at the risk of imperilling its reputation and usefulness, to neglect or slight, for any length of time, to put forth its best efforts to thoroughly indoctrinate its students in as complete and extended a theoretical treatment of the engineering subjects it teaches as the time at its disposal and the preparation of its students will permit. Drawing and designing, shop practice and testing, general culture and professional information, all are subsidiary and auxiliary to this one thing. Engineering courses at first began with little else in them of importance to the profession than this, and by it they have proved themselves indispensable to it. It is a mistake too frequently made by practitioners, deeply immersed in the details of their profession, to suppose that the most important and fruitful field of instruction is not just here.

Practice, experience, judgment will come in time to the young engineer even if he should not have it before graduation, but study and theory he will not usually thus attain to. That must be had before graduation or the engineering college has little excuse for existence.

This being granted, the fact still remains that the ultimate success of the engineer as a professional man depends upon his character and force as a man among men, upon his culture, upon his integrity, upon his tact and social power. In other professions such qualities receive continuous culture in the practice of the profession. It is far less so with the engineer. Here, then, is an argument for broad preliminary culture before entering upon engineering study, but it likewise points to something with which the engineering colleges have thus far not busied themselves to any appreciable extent, but which in the future cannot be neglected in justice to the position which the profession is called to occupy. Every engineering student has the right to careful instruction in a recognized code of professional ethics which shall instruct his conscience and fortify his will, and give him a satisfying consciousness of duty done to his professional brethren, to the public and to the judge of all the earth.

Until such instruction shall take its place in our engineering courses the public can never rely upon organized professional opinion to restrain unprofessional conduct, nor can individual members of the profession be sustained in courses of right action against the demands of corporations and combinations of capital. It remains, then, for engineering colleges to help organize the profession and to furnish the basis of such

organization in a code of professional ethics which shall be worthy, unifying and elevating.

One step further in this direction is also of importance, namely: Provision for such instruction in the law of contracts as will enable the engineer to discharge with confidence his professional obligations and protect the interests of his employers. For, it is not only necessary that he should have the scientific and technical knowledge to adapt the forces of nature to the projects in view, and exercise good judgment as to the best means of doing this, as well as have the ability fully and clearly to set forth his plans in a manner to carry conviction to those seeking his services; but it is also equally necessary that when entrusted with the responsibilities of actual construction he should be able so clearly and explicitly to set forth the rights and obligations of all parties, that disputes and legal difficulties may not arise, such as often are more costly and troublesome than errors of design. The place to obtain the necessary legal knowledge of specifications and contracts is during the professional engineering course.

It has been urged by some that economic design, as dependent upon the market price of materials, labor and power, should also find place in the engineering course, but the consensus of best opinion seems to draw the line here between education and practice. While the attention of the student should undoubtedly be drawn briefly, yet pointedly, to the economic limitations under which commercial work is done, the attempt to make designs under such limitations should be mostly left to the time when judgment has ripened and the complex conditions of practice are better known by experience. In fact, almost no undergraduate work can usefully reproduce competitive conditions, and the attempt to do this must usually be regarded with distrust. The aim of teaching is not an object lesson under business conditions, but thorough instruction in underlying principles, especially those theoretical and scientific principles which cannot be correctly estimated by the layman.

It will be noticed, in all the matters in which I have attempted to reflect the opinions which are current in the papers that have been presented to this Society and published in its proceedings, the movement and tendencies which I have sketched can be traced, all of them, to a single source, namely, to the position of influence and responsibility which the professional engineer has but recently come to occupy. That position is what it is to-day in the esteem and respect of the public largely through the wise efforts of the managers and instructors of the engineering colleges. Their work in moulding and directing the engineering education in the future will, I am persuaded, be no less important than in the past. That such guidance shall continue to be wise, its progress healthful, and costly mistakes be avoided, will be materially assisted by the deliberations and discussions of this Society.

The valuable report of the committee on entrance requirements, now in your hands, is an important piece of work, taking rank beside the other great educational reports upon the various phases of secondary education which have attracted such general attention during a few years past and have influenced so greatly the work of the preparatory schools as well as the requirements of the colleges.

I regard it as a happy omen that we are met to hold this meeting so early in our history here in Toronto, thereby expressing our interest in the promotion of engineering education as a branch of applied science, confined by no geographical boundaries or limitations, as well as our conviction that some of the most vital elements of human

progress will be moulded by the conclusions we shall reach. Let us address ourselves to the work before us with the same fraternal zeal that has characterized the meetings of the Society in the past, and that in fact is singularly characteristic of that noble body of men who practice the profession of engineering, a profession whose triumphs are our pride and whose future greatness it is the object of this Society to foster.

Henry T. Eddy.
University of Minnesota.

ANTHROPOLOGY AT THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The section was organized August 9th, as follows: W J McGee, Chairman; Anita Newcomb McGee, M. D., Secretary (elected to fill the vacancy caused by the resignation of Harlan I. Smith); W. H. Holmes, Councillor; Alice C. Fletcher (*ex officio*), M. H. Saville, Frank Hamilton Cushing and Warren K. Moorehead, Sectional Committee-at-Large; Washington Matthews, General Nominating Committee; Lightner Witmer, Stephen D. Peet and Alois Hrdlicka, Nominating Committee-at-Large.

The meetings of the section were held in the most spacious of the class-rooms in the high school building, and were well attended not only by members of the Association, but by citizens of Detroit; the attendance ranged from 50 to 400, averaging fully 200. Special interest attached to the afternoon session of August 11th, which was a joint meeting of Sections E and H, in the room assigned to the latter, for discussion of the human relics from sand deposits in Delaware valley. A number of foreign guests, members of the British Association, attended this and other meetings of the section; among them were Dr. and Mrs. Robert Munro, of Edinburgh; Professor and Mrs. J. L. Myres, of Oxford; Prince Krapotkin, of Russia, latterly of Kent, England; Dr. Albrecht Penck, of Vienna; Professor Vernon Harcourt, of Oxford, and Dr. H. P. Truell, of Wicklow, Ireland.

The afternoon of August 9th was devoted to the Vice-Presidential address, which has appeared in this Journal; and the morning session of August 10th was devoted mainly to a summary and continuation of the address, followed by a general discussion of the anthropologic classification suggested therein, in which Miss Fletcher, Dr. Munro, Professor Myres, Dr. Peet, Professor Witmer and others participated. Later a report was presented by Miss Fletcher on the Winter Conference of members of Section H held in New York last December. The section then voted to request authority from the Council to hold a formal meeting at Ithaca during the Christmas holidays of this year. (This meeting was duly authorized by the Council, and a small appropriation was made to cover cost of printing announcements, etc.)

The reading of the papers began with the afternoon session of August 10th. The first of these was an elaborate account of the superstitions, beliefs and practices of the ancient Mexicans, by Zelia Nuttall, read, in the absence of the author, by Dr. Saville. The material was mainly compiled from the records of early Spanish missionaries among the Aztecan Indians; it derived importance from the fact that these records are little known, and have not hitherto been brought to the attention of students of anthropology. The discussion by Dr. Hrdlicka and others indicated that many of the superstitions and ceremonies of the ancient Mexicans are duplicated among the more primitive peoples of different countries, notably those of central Europe.

'The Study of Ceremony,' by Dr. Washington Matthews, followed. The author expressed the conviction that the ceremonies

of primitive people are not merely worthy of scientific study, but are of sufficient extent and importance to serve as a basis for a distinct branch of science; and he illustrated his idea by describing the elaborate ceremonies of different Indian tribes and discussing the rise and decadence of fiducial practices among the American aborigines. He suggested several terms suitable for designating the study of ceremony, and invited the appointment of a sectional committee to consider the subject of nomenclature. After discussion of the paper by Dr. Peet and others, the section voted to appoint the committee suggested by Dr. Matthews, and Rev. Stephen D. Peet, Miss Alice Fletcher and Mr. Frank Hamilton Cushing were appointed as such committee.

Dr. Peet followed with a suggestive comparison of Cherokee and European symbolism, in which many curious parallels were brought out.

The next communication was 'Koreshanity: A Latter-Day Cult,' by Anita Newcomb McGee, M.D. The author described briefly a cult or religious system founded by Dr. Cyrus R. Teed, or Koresh (the Hebrew form of the prename Cyrus), and detailed the curious cosmogony bound up with the religious teaching. Although it gained foothold only within a dozen years, the doctrine has spread with such rapidity that the adherents number many hundred, perhaps thousands, of whom about 150 have entered a communistic organization with headquarters in Chicago and a colony in southwestern Florida. The communication was discussed by Professor Morse, Professor Witmer and others.

The work of the day ended with a paper on the origin of the week and holy day among primitive peoples, by Rev. R. J. Floody. Beginning with an account of the wide distribution of hebdomadal systems in different parts of the world, the author passed to explanations of the occurrence of such systems, and finally enunciated the proposition that such systems originated spontaneously among peoples in that culture-stage in which adoration of the sun, moon, etc., prevails; he held that the lunation of about 28 days is the simplest and most convenient time-measure longer than the day, and that it is naturally divisible, first into semi-lunations of relative dark and light, and then into quarter lunations defined by wax and wane with respect to full moon, 'dead' moon and intermediate half moon. An elaborate array of evidence in support of the idea, derived from primitive customs and also from folk-lore and even modern customs, was presented, and the easy development of the sacred day in connection with the moon-defined seven-day period was pointed out.

The morning session of August 11th was devoted to Mexican archæology. The first paper was a brief account, by Professor F. W. Putnam, of recent researches by George Byron Gordon on the banks of the Ulloa River in Honduras, made for the Peabody Museum. Professor W. H. Holmes followed with an account of 'The Building of a Zapotec City,' in which he sketched briefly the history of the ruined city of Mitla, as viewed from the standpoint of the builder's art. He illustrated the subject by selecting an ordinary edifice and describing the several stages in construction, beginning with the preparation of the material by quarrying and cutting the stone, passing to the masonry construction and then describing the roofing and surface embellishment; examples of the materials and of the quarrying and cutting implements—almost wholly of stone—were exhibited. Dr. Saville then noted 'The Geographic Distribution of a Certain Kind of Pottery found in Mexico and Central America;' this ware is characterized by a peculiar steel blue-gray lustre, more nearly approaching a true glaze than any surface finish heretofore

known in ancient America, of which twenty-six specimens have been found in widely separated localities from Tapec, Mexico, to Copan, Honduras; he expressed the opinion that the specimens were originally made about Alta Very Paz, Guatemala. Dr. Peet then discussed 'The Serpent Symbol in Nicaraugua,' noting the great contrast with the corresponding symbol found in the eastern part of the continent, and pointing out that in the East the serpent was generally regarded as evil or inimical to mankind, while in Nicaraugua it was considered a beneficent deity. The reasons for this diversity in belief were examined at length, and reference was made to the serpent symbol and its meaning in other parts of the world. The author expressed the conviction that, while the theory of parallel development (*i. e.*, the doctrine of activital coincidence, which has recently grown prominent, especially among American anthropologists) was strongly suggested by the facts, it could hardly be accepted as a full explanation of the similarities and dissimilarities noted. The paper was discussed by several members, notably Dr. Munro, who expressed some skepticism concerning the prevalence of serpent worship and mentioned instances of manifest error in the interpretation of artificial and even natural objects as serpent symbols. Mr. Stansbury Hagar contributed remarks concerning the Micmac and other Indians.

The afternoon was devoted to a symposium on the question of early man in Delaware valley. The Section of Geology (under Professor E. W. Claypole as Vice-President) participated. Brief papers by Messrs. H. B. Kümmel and G. G. Knapp were first presented, in the absence of the authors, by Professor R. D. Salisbury. Professor Putnam then gave a detailed account (illustrated by numerous diagrams, photographs and specimens) of the work of his assistant, Mr. Ernest Volk, in searching for human relics in the deposits about Trenton, New Jersey. It was shown that there is here a relic-bearing deposit of sand containing ferruginous bands, ranging from two feet or less to three or four feet in thickness; and photographs and other records were exhibited, showing the occurrence of artificial chips, spalls, flakes, and more or less perfect implements of argillite, quartz, etc., in this deposit to the depth of nearly or quite three feet, the abundance diminishing downward. Professor Putnam especially pointed out that, so far as his observations had gone, the artifacts of argillite predominate below, those of other materials above; he also held that these argillite objects were of the type known in Europe as paleolithic, while he regarded the more superficial artifacts as neolithic. He was followed by Professor G. F. Wright, who argued (1) that the ferruginous bands in the sand are marks of stratification, hence (2) that the deposit is water-laid, and (3) that its age corresponds with that of the later glacial deposits further northward in Delaware valley, *i. e.*, that it is Pleistocene.

Professor Holmes then exhibited a series of diagrams and other illustrations representing the geographic and geologic conditions of the relic-bearing deposits about Trenton. He first described the extensive deposit or series of deposits, reaching forty feet or more in thickness and consisting of gravel with some loam, which were undoubtedly formed during the glacial period. He pointed out that these were the deposits from which human relics were first reported at Trenton, and dwelt on the extended researches of over a dozen skilled archæologists and geologists who had been unable to find artifacts in undisturbed portions of these deposits, though they were found in the talus which unskilled observers sometimes mistook for the undisturbed deposits; and on this body of negative, yet abundant and cumulative, evidence he ex-

cluded these older deposits from consideration in connection with the question at issue. Taking up the later sand deposit, he showed that it is superficial and of limited extent, and of so slight depth as not to preclude the probability that all of the artificial material might have worked its way down from the surface; he also pointed out that this deposit appears to rest unconformably on the Pleistocene deposits, and gives other indications of being much newer. Passing then to the distribution of objects and materials, he showed that the artifacts diminish gradually and with fair uniformity downward, the distribution following the law displayed by organic matter and other substances originating at the surface; he also noted that his observations and those of his collaborators indicate no perceptible difference in frequency of argillite and other materials at the surface and at the greater depths, and exhibited photographs and specimens showing the occurrence of a finished quartz blade at about the maximum depth of human relics. In his introductory remarks and incidentally later he pointed out that, whether the artifacts be regarded as paleolithic or neolithic, they are precisely such as were found in use among the Algonquian Indians living on the site up to the time of white settlement. A brief paper by Thomas Wilson was read, in the absence of the author; it was chiefly an expression of conviction that a part of the argillite material should be classed as paleolithic.

Speaking on behalf of the geologists, Professor Claypole discussed the processes of ferrugination, and pointed out that the ferruginous bands illustrated in the diagrams and photographs could not be regarded as stratification lines, or as evidence of the aqueous origin of the sand-beds. Professor Salisbury, the geologist in charge of the State and Federal Surveys in the district, then discussed the geologic relations of the deposits; he described the thick beds of gravel and loam (which he had examined repeatedly without finding artificial material) as aqueo-glacial in origin and hence Pleistocene, and observed that the local and superficial bed of sand is younger, and was probably formed after the present river channel was excavated, at least in part, in the older deposits; he held that there was no decisive evidence that these sands were water-laid, that all of their phenomena could be explained otherwise, and that it was at least equally probable that they are eolian and perhaps quite recent. Professor T. C. Chamberlain emphasized the uncertainty as to the origin and age of the deposits developed by the elaborate studies of Salisbury, Kümmel, Knapp and others, and counseled caution in basing sweeping conclusions on so questionable premises. Dr. Penck described a somewhat parallel case in Europe, in which the question as to the age of relic-bearing deposits was set at rest by the finding of Roman objects associated with the artifacts of stone. Dr. Munro questioned whether any of the objects exhibited were paleolithic in the sense in which that term is used in Europe, and expressed doubt as to whether any trustworthy evidence of paleolithic man has been found west of the Atlantic. In response to a call, Mr. G. K. Gilbert questioned the validity of the supposed evidence of paleolithic man in Delaware valley, and mentioned cases coming under his own observation in which natural and artificial material was commingled in recent deposits.

Rising in rejoinder, Professor Putnam alluded to the discovery of an artifact beneath a large bowlder, apparently in place in the older gravels, and mentioned the finding of a human cranium, apparently of Eskimoan type, in the same deposit; and he reiterated his confidence in the prevalence of argillite materials of paleolithic character in the basal layers of the sand

beds. Professor Salisbury reviewed the geologic discussion, pointing out that the relations were such that, if the objects under consideration were fossils, no geologist would think of regarding the association as significant; and Professor Holmes recalled attention to the fact that the argillite artifacts are indistinguishable from those produced by Indians living in that vicinity up to the beginning of the present century.

The symposium was notable for the thorough knowledge of the facts displayed by several participants, as well as for the courtesy with which it was conducted.

The morning session of August 12th was opened with the exhibition of an archæologic map of Ohio by Warren K. Moorehead, who described the methods pursued in his archæologic survey of the State. The map received favorable comment throughout the section as representing the most ambitious and successful work of the kind thus far undertaken in America. The next paper, 'The Import of the Totem—a Study of the Omaha Tribe,' by Miss Alice Fletcher, was a reremarkably full yet concise memoir representing the results of thorough study. It was favorably discussed by Dr. Matthews, Dr. Peet, Professor Myers and others (it will appear elsewhere in this Journal).

The afternoon session commenced with two elaborate papers illustrated by photographs, on the Tagbanua and the Mangyan tribes of the Phillipines, by Professor Dean C. Worcester; the tribes being discussed separately by reason of important differences in their customs and beliefs. Their physical characteristics, their marriage and mortuary customs, their arts and industries and their beliefs were described in detail. Then came a full account of the anthropologic work of the New York Pathological Institute, by Dr. Hrdlicka, the Superintendent. The chief object of this work is the establishment of average or normal standards, physical, physiologic and psychologic, especially of American-born people; the methods or ancillary purposes were fully set forth and the value of the work was shown. This paper was followed by two suggestive papers by Harlan I. Smith, viz.: 'The Ethnologic Arrangement of Archæologic Material,' and 'Popular Anthropology in Museums,' read, in the absence of the author, by Dr. Saville.

On August 13th the session was opened by an attractive paper, illustrated by numerous diagrams and tables, entitled 'An Experimental Analysis of the Relations of Rate of Movement to certain other Mental and Physical Processes,' by Dr. Lightner Witmer. The results of the investigations described were full and far-reaching, and will doubtless be presented in some detail elsewhere. There followed 'A Statistical Study of Eminent Men,' by Professor J. McKeen Cattell; it was presented by the Chairman in the absence of the author. It involved the application of a somewhat arbitrary method of measuring eminence quantitatively on the basis of the space devoted to individual biographies in certain selected encyclopedias and biographical dictionaries; and, after finding the thousand most eminent men of the world in this manner, their distribution was discussed by time, race, nation, etc. The results were illustrated by diagrams. The paper was freely discussed by several members. 'A Case of Trephining in Northwestern Mexico,' by Carl Lumholtz, was presented, in the absence of the author, by Dr. Hrdlicka; it was deemed specially noteworthy as one of the most northerly examples thus far known of a primitive art which attained great development in Peru; and also because of the suggestion, derived from the form of aperture, that the operation was performed by tubular drilling something after the fashion pursued in the modern operation. The next communication was 'A Description of a Pre-Aztec Skeleton found

in Adobe Deposits in the Valley of Mexico,' by Dr. Lumholtz and Dr. Hrdlicka; it was presented by the junior author, and illustrated by photographs, diagrams and tables. The skeleton presents several remarkable features which were described in detail; in general it is of strikingly low somatic type. The characters, particularly of the skull, differ from those of the Aztec or Nahuatlan and approach those of other ancient inhabitants of the same valley, especially the so-called Toltecs. The paper was discussed at length by Dr. Matthews, Professor Morse and others, the former pointing out, by reference to many examples, the general fact that supposedly low somatic characters frequently result from the form of exercise determined by the habits of life of certain tribes; he referred especially to the olecranon perforation, which he ascribes to the custom of grinding on the metate. Several papers were then read by title, and the scientific work of the section was brought to a close by a highly suggestive communication on 'The Genesis of Implement Making,' by Frank Hamilton Cushing, which will appear elsewhere in this JOURNAL.

The session was brought to an end within the last minute of the time allotted to the sectional work at the Detroit meeting, every moment of the working time having been occupied. In a vote of thanks to the presiding officer of the section, courteously presented by Miss Fletcher, special reference was made to this activity; and in seconding the motion, ex-President Morse observed that, during the many years of his connection with the Association, he had never seen the sectional work performed with so great harmony and scientific zest.

ANITA NEWCOMB MCGEE, *Secretary.*

COLUMBIA UNIVERSITY ZOOLOGICAL EXPEDITION OF 1897.

THE results obtained by the zoological expedition sent out by Columbia University in the summer of 1896 were so valuable as to warrant a second expedition to continue the examination of the waters of the northwest Pacific coast. It was decided this year to carry the exploration to Alaska and to examine new regions on Puget Sound, in the vicinity of Port Townsend.

As before, the party obtained the most satisfactory rates from the Canadian Pacific Railroad, and it gives me great pleasure to say that the magnificence and grandeur of the scenery along the route is not the only recommendation for the road. The great care taken for the safety of their passengers, together with many courtesies and polite attentions which we received from every official with whom we came in contact, added greatly to the pleasures of the trip.

I also take this occasion to thank Lieutenant Hetherington, U. S. N., of the Bremerton Naval Station, for many courtesies shown us both before and after our arrival at Port Orchard.

The original members of the party were G. N. Calkins (in charge), N. R. Harrington, B. B. Griffin, J. H. McGregor and F. P. Keppel. Professor E. B. Wilson and Professor F. E. Lloyd joined the party somewhat later. We reached Port Townsend, which again was to be our headquarters, on the morning of June 16th. There was little to be done at this time, for our experience last year had shown that few of the marine forms were ripe so early in the season. We added a few new species, however, to our collection of last year; among them were three siphonophores (*Monophyes*, *Diphyes* and *Physophora*); one ctenophore (Beroë); five medusæ, one nudibranch mollusc; one turbellarian, a lizard and a snake, but our attention was turned mostly towards our anticipated excursions to Port Orchard, to Sitka, Alaska, and to Neah Bay. Owing to the lateness of the maturation-period in the cold waters

of Puget Sound, we decided to go to Alaska as soon as possible and to stay there as long as favorable results could be expected. We looked forward to this trip with great expectations, for every one had spoken of the richness of the fauna in Sitka harbor, where the water is more shallow than in Puget Sound and from six to ten degrees warmer. Furthermore, through the kind agency of Captain Young, of the Marine Barracks at Sitka, Captain Symonds, of the warship 'Pinta,' had offered us the use of one of the Pinta's steam launches for dredging purposes. Everything, therefore, seemed more favorable for good collecting than at Port Townsend.

In the meantime the excursion to Port Orchard was planned and executed. Port Orchard lies across Puget Sound from Seattle and consists of several bays connected by deep channels of swiftly running water characteristic of this inland sea. In some of the pockets in these bays the tides are so little felt that the water is practically still and considerably warmer than the outer waters.

The swift water of the channels promised good dredging, but unfortunately we took with us our lightest dredge which was practically useless in the current; one fine brachiopod (*Terebratulina*) alone could hardly console us in our disappointment. The best results were obtained on shore, where Mr. Griffin found quantities of *Tychodera* (a genus of Enteropneusta), while hydroids of many kinds were as characteristic as their absence at Port Townsend. We left Port Orchard with the intention of returning in August, when, with a heavier dredge, we might expect better results.

The trip to Sitka offered few chances for zoological work. Happening to reach Fort Wrangle, however, at low tide, two of the party found a number of fine specimens of *Echiurus*, a form which we had not found in Puget Sound. On a previous trip to Alaska, Mr. Calkins had found a large number of ice worms (*Dendrobœna*) on the top of Muir Glacier. Although these interesting forms have been repeatedly described, this is the first time they had been found on the Alaska glaciers. They were most numerous in the clear water of pools in hollows of the ice, although in many cases they were found deeply imbedded in the solid ice, which had to be shaved down before the animals could be reached. This year the ascent of the glacier was not only extremely difficult, but, owing to the disappearance of the ice bridge, it was impossible to get on the top of the clear ice as last year. We accordingly found comparatively few ice worms.

We reached Sitka July 14th, with the loss of one package of collecting tools, which had been dropped overboard at Port Townsend during careless handling of the freight. These tools were fished out and sent to us by the next boat. A small house by the water was soon fitted with shelves and made into a somewhat cramped but convenient laboratory. We were much disappointed to find that the 'Pinta,' having been ordered south to the repair shops, had indeed left her steam launches, but with no one to run them. There was no other steam launch available, and all dredging, therefore, had to be abandoned, save such as could be ineffectually done with a sail boat. This deprivation was much more serious than any we had yet encountered, for we soon found that Sitka harbor itself is poorly adapted for good dredging, having an extremely rough, rocky bottom. The good dredging grounds, *i. e.*, bays with sandy bottoms, such as Silver Bay, Crab Bay, etc., were too far away to be reached by sail boat, although a launch could have made the round trip comfortably in one day. We were thus forced to confine our attention to low-water collecting. In this we were very successful. The tides ran out for a considerable distance, leaving

great stretches of rock and sand exposed. The most striking thing in regard to these rocks was the richness of many-hued sponges, of Bryozoa covering rocks and weeds with fleshy or encrusting colonies; while under the rocks, in addition to the usual crabs, star-fish and annelids, rarer forms of nemerteans, echiurids and sipunculids were frequently found. The small patches of sand and shell between the rocks contained quantities of gigantic *Nepthys*, *Amphitrite*, *Synapta* and sand anemones, while in certain regions groups of *Edwardsia*, lamellibranchs and various annelids might be dug up.

On the numerous rocky islands which abound in Sitka harbor we found great numbers of sea urchins, the large *Sphærechinus* in particular, which were neatly dissected for us by the noisy ravens whenever left in the tide pools. Here, too, were found many kinds of actinians, *Thysanurans* in abundance, and various hydroids. Under the wharf and on the piles were great forests of campanularian hydroids ensnaring quantities of copepods, nematodes, nudibranch molluscs and infusoria; while on them, as parasites, gigantic acinetans were abundant. Smaller single hydroids living on mollusc shells and on the piles were added to our collections, while an occasional holothurian (*H. Californica*) might be fished out with a long pole. Professor Wilson and Mr. Harrington found this echinoderm in great abundance on a sandy bottom at Redoubt, some twelve miles from Sitka, and in them an occasional *Entoconcha*.

The rocks under the wharf were carpeted with a thick velvet of Bryozoa, chiefly *Alcyonidiidæ*, *Cellulariidæ* and *Diastoporidæ*, and many different genera were well represented. Medusæ were abundant near the shores among the eel grasses and kelp. These were chiefly anthomedusæ and leptomedusæ, although *Haliclystus*, of the order stauromedusæ was occasionally found. The 'Elbowed' medusa described by Agassiz was especially abundant, while *Polyorchis cœruleus*, scyphomedusæ and several different species of *Thaumantias* were less numerous. Large specimens of *Salpa* sometimes drifted in from the Pacific, but ascidians were less numerous than at Port Townsend.

One of the most attractive methods of collecting at Sitka was by skimming; here, at high water, the tow was wonderfully rich, a single pipette full of the sediment from one tow was found to contain quantities of pteropod larvæ, the *Mitraria* larva of Metschnikoff, the *Actinotrocha* larva, *Polygordius* trochophores, a great species of *Appendicularia*, Pilidium larvæ, a pelagic rhabdocoel turbellarian, Auricularian and Bipinnarian larvæ, etc.

The collection and preservation of these interesting and often rare forms was not the only line of research. Cytological material for many different investigations was preserved. This included a series of maturation and fertilization stages of *Sphærechinus*, maturation and fertilization of *Edwardsia*, maturation material of *Thaumantias*, material for spermatogenesis of *Nepthys*, a full set of material for the development of medusa buds of *Plumularia*, maturation material of *Echiurus*, of *Holothuria*, maturation and fertilization of eggs of a lamellibranch, growth and embryological material of a tunicate, etc. In addition to this, notes were kept on the distribution of forms on rocks, piles or pelagic, and of course many notes on the habits, appearance and movements of the living animals.

Taking all into consideration, however, we are forced to the conclusion that, for shore collecting at least, Sitka is less favored than Port Townsend, where the great stretches of tide flats, shaded by long lines of wharves with innumerable piles, offer advantages for shore collecting hardly to be

surpassed. What our impression of Sitka might have been had we had the use of a launch for dredging can only be inferred; from the nature of the littoral fauna and from the pelagic forms it seems as though we might have found great richness at depths from five to twenty fathoms.

Owing to our limited resources for collecting at Sitka, and to the desire to get back to Puget Sound in time for embryological investigations, we decided to return to Port Townsend at the end of three weeks. Here we were met by an unforeseen difficulty. It was in the very midst of the tourist season, and in addition to the usual tourists many Christian Endeavorers had taken the opportunity to visit Alaska. The result was that the regular boats were overcrowded, and our only chance of getting away at the time desired was on some steamer coming north with miners and returning light. Such a chance was offered by the 'Mexico,' an extra boat put on to meet the rush to the Klondike. The 'Mexico' arrived at Sitka August 3d, after leaving about 300 miners at Skaguay and Dyea, and, as anticipated, she was practically empty for the return trip.

The captain of the 'Mexico,' who had lost time on the trip north, wanted to save time on the return trip, and decided to take the outside passage from Sitka, thereby saving sixteen hours on the usual time of the inside passage. It was the intention at first to enter the inside passage north of Mary Island, but later it was decided to run down to Dixon Entrance before leaving the open Pacific. We reached the entrance about midnight, but a light fog had settled, and for some hours the pilot caused the vessel to beat around at half speed or else to lie quiet. The water was too deep to anchor, and the effect of the strong currents on the vessel's course was not properly reckoned, for at four o'clock in the morning of August 5th the order was given to go ahead at full speed, and twenty minutes later the 'Mexico' crashed into West Devil Rock, a charted rock some distance (3–7 miles) out of the regular course. The hole made in the bottom of the vessel was beyond question of repair, and at 6.30 a. m. she sank out of sight in 500 feet of water.

After eighteen or twenty hours in the open boats the passengers were landed at the Indian village of New Metlahkatlah, where they were taken care of by the Indians and their chief, Father Duncan, until the 'Topeka' called for them, two days later, and carried them back to Puget Sound. Nothing was saved but the hand baggage; most of the instruments and all of our scientific material, reagents, notes, books and theses, representing not alone the summer's work, but unfortunately also much work of the previous year, now lie at the bottom of Dixon Entrance.

Without reagents and instruments and feeling more or less upset by the shock of the wreck, the entire party found it difficult to settle down again for work. A few dredging trips, however, enabled Mr. Harrington to renew his supply of *Entoconcha*, while turbellaria, molluscs and some cœlenterates were found in full maturity. The party soon broke up, and the material collected at Port Townsend and Port Orchard alone represents the work of the expedition of 1897.

GARY N. CALKINS.

*MIMICRY IN BUTTERFLIES OF THE GENUS HYPOLIMNAS AND ITS BEARING ON OLDER AND MORE RECENT THEORIES OF MIMICRY.**

THE theory of mimicry suggested by H. W. Bates, in 1862, explained the superficial resemblance of a rare to a common species in the same locality by supposing that the latter possessed some special means of defence (such as unpleasant taste, smell, etc.),

*Abstract of a paper presented by E. B. Poulton before the Section of Zoology of the American Association for the Advancement of Science.

and that the former, without the special defence, was mistaken by enemies for the latter, and thus escaped a considerable amount of persecution. The relation may be compared to that existing between a successful well-known firm and another small unscrupulous one which lives upon its reputation. On the other hand, Bates thoroughly recognized the existance of resemblances between the specially defended forms themselves. These he could not explain by his theory of mimicry, and suggested that they were a result of the influence of locality. Many years later Fritz Müller satisfactorily explained this difficulty by suggesting that a common type of appearance simplified the education of enemies and thus was the means of saving life. The lives of many individuals must be sacrificed before enemies have learned to recognize and to avoid the colors and patterns which indicate some special means of defence, and the fewer such patterns in any locality the smaller the sacrifice. The relation may be compared to that between two successful firms which combine to use a common advertisement.

This latter theory, although received rather coldly at first, has gradually made way, and seems now likely to occupy a good deal of the ground formerly believed to be covered by the former theory. Thus, Dr. F. A. Dixey, of Oxford, has recently shown that South American *Heliconinæ* are affected by the color of certain *Pierinæ* which have hitherto been looked upon as true Batesian mimics of the former.

The Old World Nymphaline genus *Hypolimnas* has been regarded as one of the best examples of mimicry, but an unbiased examination leads to the opinion that it affords a case of Müllerian rather than Batesian resemblance.

In India the female of the common species *H. bolina* resembles *Euplœa Core*, while the male is a dark butterfly with a large white spot shot with blue on each of the four wings. Throughout the Malay Archipelago representative species occur with males like that of *H. bolina* and females resembling the local *Euplœas*. Occasionally, as in Ké Island and the Solomons, species of the genus occur in which the male as well as the female resembles a *Euplœa*. In Fiji the male is as in the Indian species, while the female is extremely variable, ranging from forms like the male through intermediate varieties to brown and straw-colored individuals. The *Euplœas* of Fiji are not sufficiently known, but it is very improbable that all the forms of the female *Hypolimnas* are mimetic. A still more instructive case is that of the *nerina* form of female found, with a male like that of *H. bolina*, in Australia, Celebes, New Guinea and other East Indian islands and in many of the Polynesian groups. This conspicuous and abundant butterfly has, in addition to the four white-and-blue spots of the male, a large reddish brown patch upon each forewing. This well-marked form resembles no other butterfly except the *Danais chianippe* of Celebes, and, as this latter appears to be very rare, it is far more probable that the resemblance has come from the other side, and that the *Danais* has approached the *Hypolimnas*.

In Africa the subgenus *Euralia* is represented by several species which resemble in both sexes species of the Ethiopian Danaine genus *Amauris*.

Finally, there is a well-known and widespread *Hypolimnas misippus*, which accompanies *Limnas chrysippus* throughout its range; while the female of the former resembles the latter very closely. In this case it is certain that we have to do with no struggling, hard-pressed form, for the *Hypolimnas* has recently established itself in some of the West India Islands and in Demerara —localities in which its model, *L. chrysippus*, is as yet unknown.

To sum up, the genus *Hypolimnas* is distinguished among Nymphaline genera for the extent to which its numerous and widespread species resemble the local distasteful forms of Euplœinæ or Danainæ.

Upon the older theory of Bates this would be explained by supposing that the genus is very hard-pressed in the struggle, and has thus been driven to mimicry almost everywhere. Upon the newer Müllerian theory it is supposed that the genus is distinguished among Nymphaline genera by some special defense, probably in the way of taste or smell or indigestibility, and that it has been to its advantage to adopt the advertisement of still better known and probably still more distasteful forms in its locality.

The abundance of the various species, the conspicuous *nerina* form of female, and the resemblance of a rare Danaid to it, the recent spread of *H. misippus* beyond the limits of its model, all support this latter interpretation.

NOTES ON ENGINEERING.

THE cost of power in New England cotton mills has been, of late, the subject of some discussion in technical and lay journals. The lowest cost yet reported, with one exception, is that given by Mr. Sheldon for the case of a mill which, paying $1.76 per ton for coal, obtained the horse-power for a total cost per annum, including all items on the treasurer's books, interest, depreciation, taxes, etc., of $11.64.

This figure was challenged and compared with the items generally given for other classes of engine which are usually two or three times as great and often much more. But the latest report comes from the Warren Steam Cotton Mill, where an engine of 1,950 horse-power, a cross-compound condensing machine, with cylinders 32 and 68 inches diameter and of five-feet stroke of piston, making 74 revolutions per minute, steam at 155 pounds at the boiler, supplies power at the cost of 1.35 pounds of coal per horse-power hour. The engine was designed by Edwin Reynolds, the boilers built by the Heine Company. The following are the figures certified to Dr. Thurston by the treasurer of the mill. The engine replaces a quadruple-expansion engine, destroyed by fire, after seven years of excellent service. The change illustrates the fact that the cost of the higher grade of machine may more than compensate its exceptional economy; a fact which has only in late years come to be recognized.

In the following table of the costs of the new engine the figures come from the treasurer's books. Coal costs $2.26 per ton, and in the account includes all costs of all steam used for all purposes, including banked fires, nights and Sundays, and that supplied the mill.

The following is a tabulated statement of the cost of power:

Fuel per horse-power per year of 3,070 hours	$ 4 70
Labor	1 88
Supplies and repairs	42
Total operating expenses	$ 7 00
Interest at 5 per cent	$ 2 05
Depreciation, at 5 per cent	2 05
Taxes	41
Insurance	04
Fixed charges	$ 4 55
Totals cost of power per year	$11 55

According to the Providence (R. I.) *Journal:* "This is lower than anything yet found. It is due to the large size of plant, which reduces the labor and supply account per horse-power, and to low cost of fuel and insurance and low cost of plant, on account of its size. The cost of plant includes a Green economizer, chimney, boiler-house, engine-house and foundations—all first class—and water-tube boilers, whose depreciation ought not to be over 2½ per cent. If steam used for other purposes than power were deducted, it would reduce the fuel 10 per

cent., or 47 cents per year, per horse-power, making the total $11.08. There is no way of separating this amount from the total in the regular accounts."

So far as known, this is the lowest cost of steam-power in any New England textile mill. The tons fuel per horse-power per year is 2.08—the lowest noted; others run about 2.20 tons per horse-power and upward.

R. H. T.

SCIENTIFIC NOTES AND NEWS.

Professor Michael Foster will deliver several lectures in Baltimore in October and will visit Boston later to deliver a course of lectures at the Lowell Institute.

Professor James E. Keeler, of the Allegheny Observatory, has accepted an invitation to make the dedicatory address at the opening of the Yerkes Observatory.

Dr. Fridjof Nansen is expected to arrive in New York on the steamer St. Paul, on October 23d. After visiting Washington as the guest of the National Geographic Society, he will give his first lecture in Carnegie Hall, New York, on October 28th. At the close of the lecture a medal will be presented to him by the American Geographical Society. The collections now at Stockholm will be brought to America and exhibited here.

Sir William Turner, President of the Anthropological Section, of the British Association for the Toronto meeting sailed from Montreal on the 22d. He will in future devote his time less to histological and more to anthropological researches.

We regret to notice the death of Dr. Holmgren, since 1864 professor of physiology in the University of Upsala, at the age of sixty-six years.

The following deaths are also announced: Dr. August Mojsisovics Edler v. Mojsvar, professor of zoology in the Polytecnic Institute at Graz; Mr. William Archer, F.R.S., librarian of the National Library of Ireland; Dr. T. Bogomoloff, professor of medical chemistry in the University of Kharkoff; Dr. John Braxton Hicks, F.R.S., one of the pioneers of British work on diseases of women, and a Fellow of the Royal Society since 1862.

The British Association, at the recent Toronto meeting, granted £1,350 for scientific research. We hope to give next week details of the appropriations.

The French Academy has accepted a legacy from M. Pierre Lassere amounting to over $100,000; the income from one-third of this sum is to be awarded by the Academy of Sciences for a scientific discovery.

A small fund, founded in memory of Surgeon-Major Arthur Barclay, is to be used for a bronze medal to be awarded every third year by the Asiatic Society of Bengal for the most meritorious piece of work done in original research in biology, with special reference to India.

A bronze monument, erected in honor of Marcello Malpighi, the eminent Italian anatomist and botanist of the seventeenth century, was unveiled at Crevacore, near Bologna, on September 8th.

The new museum of the Brooklyn Institute of Arts and Sciences will be dedicated on October 2d. Addresses will be made by President Eliot, of Harvard University, and by Mayor Wurster, of Brooklyn. There will be a reception in the evening in the Academy of Music.

It is reported that plans have already been made for the new building of the American Geographical Society, New York, although the site has not yet been decided upon. The present building in West 29th street, purchased in 1875, has long been outgrown by the Society, and it has assets amounting to nearly $400,000. The Society owes its present position and great growth to Judge Daly, who for thirty-three years has been its President.

The Greek Archæological Society has secured possession of a quarter of Athens lying immediately under the Acropolis. The inhabitants will remove to the suburbs, and excavations promising important discoveries will begin shortly.

A series of seven kites of the Hargrave type, sent up from the Blue Hill Observatory on Sep-

tember 19th, reached a height of 9,386 feet above the summit of the hill, this being the highest ascension thus far made. The kites carried an aluminium box with instruments for recording temperature, pressure and humidity, and the records are a further demonstration that kites may become a valuable addition to the methods of meteorology.

A MICROTOME for making sections of the entire human brain is being constructed by Messrs. Bausch and Lomb on the pattern of the 'automatic precision microtome,' recently described in our pages. The manufacturers expect that the new instrument will make large sections of greater thinness and accuracy than it has been possible to obtain hitherto.

THE *Atlantic Monthly*, 'devoted to literature, science, art and politics,' has completed its fortieth year with the current number and publishes an editorial retrospect eight pages in length. Its scientific work is thus described: "In 1862 scientific articles by Agassiz began to appear, and a long succession of his writings was brought to an end by a paper published in 1874, just after his death. Even if the *Atlantic* had done nothing else in the field of science this record would be worth making; but the great achievements of these later years have always formed an important part of its contents, and have been related by men like Rodolfo Lanciani, Percival Lowell, N. S. Shaler, G. F. Wright and T. J. J. See, who has a notable article in the present number." Compared with the men of letters mentioned by the *Atlantic Monthly* this list indicates that its devotion to literature has exceeded its devotion to science.

THE New York State Library Association, at its meeting in 1896, recommended the fifty books of 1895, regarded as best for a village library. The scientific books included are as follows: Edward Clodd, 'Story of primitive man;' Percival Lowell, 'Mars;' S. H. Scudder, 'Frail children of the air;' M. O. Wright, 'Birdcraft;' Philip Atkinson, 'Electricity for everybody.'

THE University of the State of New York has published the report of the Public Libraries Division for 1896, which gives a complete and interesting survey of the growth of libraries in the State. 806 libraries of 300 volumes or more have sent in reports. These libraries contain a total of 4,647,661 volumes, of which number 296,498 were added during the year. The libraries in the State having over 100,000 volumes are as follows:

New York, N. Y., Public Library, Astor, Lenox and Tilden foundations 367,808; New York, Mercantile Library, 253,783; Albany, New York State Library, 223,547; New York, Columbia University Library, 223,000; Ithaca, Cornell University Library, 186,683; Brooklyn, Brooklyn Library, 124,-299; New York, General Society Mechanics and Tradesmen Library, 106,440.

The libraries that added over 10,000 books during 1896 are as follows:

Columbia College Library, 20,580; New York Public Library, 15,594; New York State Library, 14,570; Cornell University Library, 13,578; New York Free Circulating Library, 11,201.

THE Minnesota Child Study Association, organized in 1895, has published a hand-book of 60 pages, which may be secured for 30 cents from the Secretary of the Association, Mr. E. A. Kirkpatrick, Winona, Minn. The pamphlet contains a number of suggestions and syllabi for the study of children, which will prove useful, more especially in view of the lack of a systematic treatise on the subject.

IN a letter, lately published, from Mr. Voorhes, Vice-President, to Mr. Charles H. Fahl, the engineer of the train, the former gives the figures for the runs of the train between Camden and Atlantic City last season, and gives deserved credit to the engineer. The facts are most remarkable and creditable, and the action of the Vice-President of the road is commendable in a remarkable degree. Were it an ocean steamer of which the performance was thus described the credit would have been given solely, in the usual case at least, to the commanding officer; the engineer would have been forgotten. Mr. Voorhes says: "The train record shows that for the fifty-two days the train ran, from July 2d to August 31st, the average time consumed on the run was forty-eight minutes, equivalent to a uniform rate of speed, from start to stop, of sixty-nine miles an

hour." * * * "This performance, I believe, has not been equaled in the history of railway service, either in this country or abroad. It is one of which the management is proud, and is accredited to the track, the equipment, and, especially, to the skill with which you performed the task entrusted to you." The distance was fifty-five and a-half miles, and the train consisted of five or six cars. It was always delayed by its connections at starting, and always came in ahead of schedule time; the total thus being brought four minutes under schedule time. The thanks of the railway officials are tendered Mr. Fahl.

THE Congrès Olympique recently held at Havre has passed resolutions summarized in the *British Medical Journal* as follows: Every three months parents are to be informed of the physical development of their children being educated in schools and colleges. That hygiene, physical training and athletic sports should be introduced in all schools, *lycées* and colleges. In all schools, colleges and *lycées* a service of hydrotherapy should be in working order. That a diploma for gymnastics be created, requiring a practical and oral examination.

THE Eleventh International Congress of Orientalists has held a successful meeting in Paris, many important archæological papers having been presented and plans having been made for further explorations in the East.

THE Council of the Society of Arts have appointed the following Committee to investigate the causes of the deterioration of paper: Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I., Chairman of the Council; Sir William Anderson, K.C.B., F.R.S.; Mr. Michael Carteighe; Mr. C. F. Cross; Sir John Evans, K.C.B., F.R.S.; Dr. Richard Garnett, C.B.; Dr. Hugo Müller, F.R.S.; Dr. J. W. Russell, F.R.S.; Mr. W. L. Thomas; Professor J. M. Thomson, F.R.S.; Mr. Henry R. Tedder; Dr. Quirin Wirtz; Sir Henry Trueman Wood, Secretary. *Nature* states that, in the course of a circular letter which has been sent to those who are interested in the preservation of paper, it is pointed out that many books of an important character are now printed upon paper of a very perishable nature, so that there is considerable risk of the deterioration and even destruction of such books within a limited space of time. This is believed to be especially true of books which are in constant use for purposes of reference, and are therefore liable to much handling.

ACCORDING to the New York *Tribune* the most interesting work now going on at the Weather Bureau is the preparation of an exhibit of this Bureau for the Paris exhibition in 1900. Professor Moore is taking a deep interest in the matter, and, as planned, it will be one of the largest and most complete expositions of this character ever made. A feature of the exhibit will be a daily weather chart of the United States. A code has been adopted by which the conditions of the weather in all parts of the United States will be transmitted by telegraph to Paris. From the material thus obtained maps will be constructed on the order of those now in general use. Professor Moore, with five or six of his subordinates, will represent the Weather Bureau at the exposition, and nothing is being left undone to make a showing worthy of the United States Bureau, which is acknowledged by scientific authorities to be the finest in the world.

LIEUTENANT PEARY, on arriving at Philadelphia, is reported to have said that in addition to securing the meteorite he laid the plans for next year's expedition, and when he leaves again, which will be about the end of next July, it will be to remain in the Arctic regions until he reach the Pole or lose his life in the attempt, even if it take five years to accomplish this object. Next summer he will take his vessel up to Sherard Osborne Fjord and make that place his base of supplies. On the last trip he made arrangements with the Arctic Highlanders, a tribe of Esquimaux consisting of 230 men, women and children, known as the most northerly tribe of human beings on the earth, to spend this coming winter in obtaining bear, seal and deer skins for clothing and in securing all the walrus meat they can for dog food. He has singled out eight young men of the tribe, with their wives, canoes, dogs, sledges and tents, to accompany him to Sherard Osborne

Fjord, which is about three hundred miles further north than their present abode. The party will consist of a surgeon, possibly another white man and Lieut. Peary; the rest will be Esquimaux. The latter know how to drive dogs; they can go hungry and know how to get food. The conditions under which he will make the coming expedition are of the most satisfactory character. The American Geographical Society has assured $150,000 to meet all expenses. Lieutenant Peary has five years' leave of absence. He will probably buy a new ship for next year, though he may possibly use the Hope again.

UNIVERSITY AND EDUCATIONAL NEWS.

INSTITUTIONS FOR HIGHER EDUCATION IN THE UNITED STATES.

The report of the Commissioner of Education for the year 1895–6 reports that the total number of universities and colleges for men and for both sexes reporting during the year was 484, of which number 345 admit women to undergraduate courses of study. There are 188 institutions which have not as yet any endowment; 54 have endowment funds less than $25,000, and only 4 institutions have endowments exceeding $5,000,000. In a large number of the institutions a comparatively small part of the work is collegiate. There are at present 278 institutions having less than 100 students in undergraduate collegiate courses. The number of instructors reported by the 484 institutions was 12,277, while the number of students of all classes, secondary and higher, was 159,372. Of the latter number 47,014 were in preparatory departments, 68,629 in collegiate departments, 4,673 in graduate departments and 25,438 in professional departments. The property reported was as follows: Volumes in libraries, 6,453,677; value of material equipment, $134,093,435; endowment funds, $109,562,433. The benefactions for the year, so far as reported, amounted to $8,342,728, and the income, excluding benefactions, was $17,918,174.

The 162 colleges for women had, in 1894–'95, 2,552 instructors and 24,663 students. The material equipment was valued at $15,568,508, and the endowment funds amounted to $5,308,558. The income was $3,456,983, and the benefactions received during the year amounted to $611,245.

The number of schools of technology, excluding technological departments of universities and colleges, was 48, having 1,118 instructors and 12,816 students. The total value of all property was reported at $24,105,242, of which amount $10,384,293 was reported as endowment funds. The income of these institutions was $3,526,018, of which amount $2,402,332 was appropriated by the General and State governments. The gifts and bequests received by the schools of technology amounted to but $96,133.

The increase in attendance at these universities and colleges is shown in the accompanying figure:

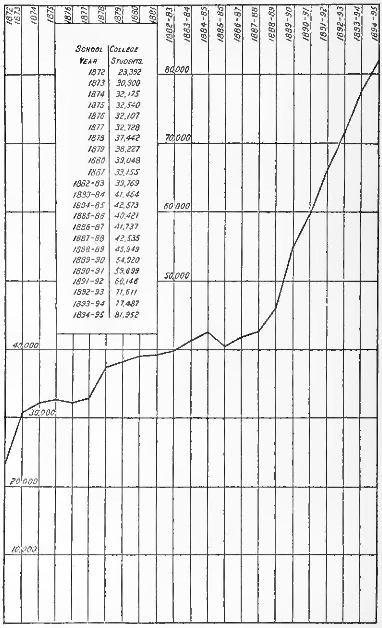

Fig. 1. The increase in attendance at American universities and colleges from 1872 to 1894-5.

GENERAL.

IT is reported that Harvard College and the Massachusetts Institute of Technology will each receive about $500,000 from the estate of the late Henry O. Pierce, under whose will they are, together with three other institutions, the residuary legatees. The amount to be divided has proved much larger than had been anticipated. The value of these bequests is much increased by the fact that they are unaccompanied by restrictions.

THE will of the late Eliza W. S. P. Field gives $80,000 to the University of Pennsylvania, and makes the University residuary legatee of her estate.

MRS. ESTHER B. STEELE, of Elmira, N. Y., has given $5,000 towards the cost of a physical laboratory for Syracuse University. The building, which will cost about $25,000, will be erected shortly.

FURMAN UNIVERSITY, at Greenville, S. C., has been given by Dr. and Mrs. F. A. Miles real estate valued at $20,000.

THE will of Theodore Lyman, whose death we were recently compelled to record, bequeathes $10,000 to Harvard University and a collection of valuable books to the Museum of Comparative Zoology.

EX-GOVERNOR FLOWER has given $5,000 to Cornell University for the purpose of a library for the Veterinary College.

THE will of the late Henry W. Sage, lately President of the Board of Trustees of Cornell University, to which institution he had given about $1,250,000, disposes of property worth $12,000,000, but makes no public bequests.

DR. ELISHA GREGORY, JR., formerly demonstrator of anatomy at the University of St. Louis, has returned, after a year's study in Germany, to enter upon his duties as instructor in histology and embryology at the Harvard Medical School.

PROFESSOR PETER T. AUSTEN has left the department chemistry at the Polytechnic Institute, Brooklyn, and is succeeded by Professor Fay.

MR. C. H. BENEDICT has been appointed instructor and Mr. J. M. Talmage assistant in chemistry in Cornell University.

AT a meeting of the regents of the University of the State of California the resignation of Professor Colton from the staff of the Lick Observatory was accepted.

THE following appointments have been recently made: Dr. Weiss, professor of mathematics in the Institute of Technology at Prague; Dr. Herzig, associate professor of chemistry in the University of Vienna; Dr. Zelinka, of Graz, professor of zoology in the University at Czernowitz; Dr. Zwaardemarker, professor of physsiology in the University of Utrecht; Dr. Julius Hann, director of the Vienna College of Meteorology, professor of meteorology at Graz, in Styria; Professor Joseph Pernter, professor of cosmical physics in Innsbruck University, appointed to the vacancy caused by Dr. Hann's retirement from the Vienna College; Dr. W. Ernest Thomson, professor of anatomy in Anderson College, Glasgow, and M. Brunhes, professor of physics in the faculty of science at Dijon.

THE Cambridge University Calendar shows that the undergraduates in residence at the University now number 2,928, of whom 664 are members of Trinity College and 264 of St. John's.

THE *Athenæum* says that a proposal is being considered to establish at Swansea, as a great manufacturing center, a branch University College in association with either Aberystwith or Cardiff, as the Newcastle College is associated with Durham. The suggestion is that scientific and technical courses might be taken at Swansea in preparation for the Welsh University degree.

DISCUSSION AND CORRESPONDENCE.

METEOROLOGY IN SOUTH AMERICA.

TO THE EDITOR OF SCIENCE: During the writer's present trip down the eastern coast of South America, he has gathered a few facts regarding meteorological work on this continent which may interest the readers of SCIENCE.

The only complete meteorological service in

South America is that of the Argentine Republic, with headquarters at Cordoba. The Argentine meteorological office, established by the late Dr. B. A. Gould, has, since the date of Dr. Gould's resignation as its director (1883), been under the direction of Mr. W. G. Davis. This service has at the present time nine first-order stations, fifty-eight second-order and one hundred and twenty-six third order. Of the first order stations, the most interesting in many respects, is that on the Isla de los Estados (Staten Island), off the southeastern extremity of South America, where the meteorological conditions present many unusual features. In addition, Mr. Davis will soon have in operation six new mountain stations, reaching from Patagonia along the Cordilleras into northern Argentina. These new stations will, in connection with the Harvard meteorological stations in Peru, form a splendid series along the western coast of South America.

As yet the Argentine meteorological service makes no attempt to publish a daily weather map or to issue forecasts, the director believing that his first duty is to establish and equip his stations, and to study the general climatological features of the region. *The Anales de la Oficina Meteorologica Argentina* already number nine large volumes, containing meteorological data as to the climate of Argentina. Vols. X. and XI. are now in press, and contain, among other data, the observations made on the Isla de los Estados, and a discussion of them. In addition to the ordinary work directly connected with the weather service, the director has made studies of the climatic conditions of different parts of the country as bearing on the raising of various crops, on the manufacture of cotton, etc., and of the relation between atmospheric conditions and disease in Buenos Ayres and Cordoba. The physiological effects of different weather types have also been studied. The forthcoming census of Argentina will contain chapters on the climatology of the country, illustrated by charts, also the work of the director. The observers of the Argentine meterological service now receive ten dollars (paper) a month for their services, and it is the policy of the director to do all he can to keep them interested in their work and to secure as accurate observations as possible from them. He accomplishes this by constant personal correspondence with the individual observers, and by sending them such meteorological books as they may wish to see and which he is able to loan them. At present, for instance, he is sending out eighty copies of the new cloud atlas to the observers. Such a policy is worthy of adoption by other weather services.

In 1882 the capital of the province of Buenos Ayres was removed from Buenos Ayres to the new city of La Plata, in Latitude 34° 55′ S., Longitude 57° 54′ W. Here an observatory was built for carrying on astronomical, magnetic and meteorological work, and a provincial weather service has been organized under the direction of V. Bœuf. The headquarters are at La Plata, and there are at present some sixty stations in all. Sixteen of these take the ordinary observations at 8 a. m. and 8 p. m., and report by telegraph to La Plata every morning, while the remaining (pluviometer) stations report wind direction, cloudiness and rainfall. The La Plata Observatory publishes a daily weather map, based on these data, and this is the only map of the kind at present issued in South America. This is no forecast, and the map relates solely to the province of Buenos Ayres, and not to the republic as a whole. The chief office has a poor instrumental equipment, there being, at the time of the writer's visit, no self-recording instruments in operation. Cloudiness is estimated in quarters of the sky covered, instead of in tenths, as is usually the case. Hourly observations are made at La Plata every hour from 6 a. m. to 8 p. m.

At Rio de Janeiro meteorological observations are regularly made at the National Observatory, situated on the most easterly hill of the city, overlooking the harbor. The instrumental equipment is good, and observations are made eight times in every twenty-four hours (1, 4, 7 and 10 a. m. and p. m.). The observatory is under the direction of L. Cruls, who also has charge of the geographical and geodetic work of the republic. The meteorological observations have been published in various volumes of the *Annales de l'Observatoire*. M. Cruls has lately been the chief of a commission appointed

to inquire into and report upon the availability of a new site for the national capital. According to the Federal Constitution the capital must be removed from Rio de Janeiro to a more healthy location in the interior province of La Goyaz, at a considerable altitude above sea level. The above-mentioned commission has published an elaborate report, finely illustrated with photographs and charts, in which the geology, hydrography, climatology, etc., of the new site receive consideration. The work is a very interesting one.

Owing to the unfavorable atmospheric conditions at Rio, where the cloudiness is very considerable, there has for some years been a plan to remove the Observatory to a new location near Petropolis, in the Organ mountains, at an altitude of over 2,700 feet. Petropolis is a place much sought by the wealthier classes of Rio during the summer months, when yellow fever is most prevalent in the capital. It is high enough to be above the yellow fever zone, and its cool evenings and nights are much more agreeable than the hot nights of Rio. Furthermore, it is above the fogs which commonly hang over Rio harbor at night, and is therefore a much more favorable location for an astronomical observatory. The necessary funds for the removal are, however, lacking, and there is at present no prospect that the location of the Observatory will be changed.

There is a very common belief that the *climate* of Rio is unhealthy. This is by no means the case. The climate itself is a fine one in many ways, the unhealthy character of the city being due simply to the lack of attention to the simplest sanitary measures. Rio harbor itself, beautiful as it is, is the most deadly feature about the whole place. The waters are so foul, as a result of the improper disposal of the city's sewerage, that they are a veritable storehouse of disease. When the city adopts proper sanitary regulations and builds sewers to empty its drainage into the open ocean, instead of into the harbor, then Rio will become as healthy as a city with its beautiful situation deserves to be.

This letter is mailed in the Falkland Islands. Although the meteorology of these islands is most interesting, regular observations are no longer made here. Those made here in the past have been discussed by Marriott (Quart. Jour. Roy. Met. Soc., London, 1880), and by von Dankelmann (Ann. d. Hydrog, Berlin, 1885). Mr. Davis, of the Argentine meteorological office, has sent two sets of instruments to the islands, but has not yet succeeded in securing regular observers. The climate of the islands is particularly interesting by reason of their far southerly position in the stormy prevailing westerlies of the southern hemisphere. Sunshine is so rare here in winter that, as an old resident of Port Stanley said to the writer to-day, "When we see the sun for an hour or two everyone says 'what fine weather we are having.'"

R. DEC. WARD.

PORT STANLEY, FALKLAND ISLANDS, July 29, 1897.

SCIENTIFIC LITERATURE.

Memoirs of the American Folk-Lore Society. Vol. V., 1897. Navaho Legends, Collected and Translated by WASHINGTON MATTHEWS, M.D., LL.D. With Introduction, Notes, Illustrations, Texts, Interlinear Translations, and Melodies. Boston and New York, Houghton, Mifflin and Company. Pp. 299.

A study of aboriginal life from the pen of Dr. Washington Matthews is always welcome, and this volume of Navaho Legends is no exception to the pleasant rule. Out of the abundant material collected by the author he has selected three legends for this publication: two incomplete rite-myths and the Navaho Origin Legend. The latter 'divides itself into four very distinct parts,' I. The Story of the Emergence; II. Early events in the Fifth World; III. The War Gods; and IV. The Growth of the Navaho Nation. The term rite-myth is defined as 'a myth which accounts for the work of a ceremony, for its origin, for its introduction among the Navahoes, or for all these things.'

The Navahoes, we are told, "celebrate long and costly ceremonies, many of which are of nine days' duration. Each ceremony has connected with it one or more myths, or legends which may not be altogether mythical." These rite-myths possess a degree of traditional value, and the last chapter of the Origin legend, our author says, 'is in part traditional or historical, and is even approximately correct in many of

its dates.' This group of legends, therefore, belongs to a class, the knowledge of which is indispensable to a reconstruction of the past life of a tribe, or to the understanding of existing conditions of the people, or to the tracing of the contact and interrelations of tribes prior to the historic period of this continent.

The introduction, and more particularly the volumious notes, in the preparation of which the author had in mind their 'interest to the ethnographer,' are replete with information. They explain, more or less in detail, customs mentioned incidentally in the legends, and cite the evidence by which localities referred to in the text have been identified. They also contain extracts from varients of the legends, and note other rites and myths in which figure the divinities of the narrative, and give numerous linguistic and other explanations of names, rites, customs, etc., which put the reader in possession of knowledge invaluable for the study of these Indians. The breadth of view of the subject treated is enlarged by abundant cross references, both to matter within the volume and to other writings of the author upon the Navahoes, a complete list of which is included in the Bibliographic Notes compiled by Mr. F. W. Hodge, forming a part of the book.

In presenting these legends to the public the author has "not confined himself to a close literal translation. Such translation would often be difficult to understand, and, more often still, be uninteresting reading. * * * The tales were told in fluent Navaho, easy of comprehension, and of such literary perfection as to hold the hearer's attention. They should be translated into English of a similar character, even if words have to be added to make the sense clear. * * * If he has erred in rendering the spirit of the savage authors, it has been by diminishing rather than by exaggerating. * * * In order that the reader may judge how closely the liberal translation here offered follows the original, the Navaho text of the opening passages—ten paragraphs—of the Origin legend, with interlinear translations, are given in the notes."

Fifteen pages or more of these interlinear translations afford an opportunity to observe the construction of the language and its use in narrative, ritual and song.

The examples of Navaho songs are interesting, not only in relation to the legends and the use of the language with poetic intent, but because they show that the same device obtains among the Navahoes which is common with the Indians of the Siouan linguistic group, a device to produce the effect of rhyme by means of certain 'meaningless vocables' at the close of each sentence. In his introduction, Dr. Matthews calls attention to the use of archaic words in the songs, to which 'the priests assign traditional meanings;' and also to the 'numerous meaningless vocables in all songs,' which 'must be recited with a care at least equal to that bestowed on the rest of the composition.' The same precision is required in the repetition of the vocables in the songs of the Siouan group. The writer having discovered that the emotional prompting of the song decides the choice of these vocables, it is especially interesting to note that, making allowance for the wide difference of language, the vocables given in the Navaho songs seem to follow the same rule that appears to govern their use among the northern tribes.

The short essay by Professor John Comfort Fillmore, upon the music—included in the notes—is of peculiar interest. His extended experience with Indian songs, added to his scholarly attainments in music, makes whatever he has to say upon this subject worthy the careful consideration of those interested in this phase of ethnological research. To quote from Professor Fillmore, Note 272, speaking of the songs transcribed from the phonographic records taken by Dr. Matthews, "they have very great scientific interest and value, inasmuch as they throw much light on the problem of the form spontaneously assumed by natural folk songs. Primitive man, expressing his emotions—especially strongly excited feeling—in song, without any rules or theories, must, of course, move spontaneously along the line of least resistance. This is the law under which folk-melodies must necessarily be shaped. The farther back we can get toward absolutely primitive expression of emotion in song, the more valuable is our material for scientific

purposes; because we can be certain that it is both spontaneous and original, unaffected by contact with civilized music and by any and all theories. In such music we may study the operation of natural psychical laws correlated with physical laws, working freely and coming to spontaneous expression through the vocal apparatus.

"These Navaho songs are especially valuable because they carry us well back toward the beginnings of music making. One only needs to hear them sung, or listen to them in the admirable phonographic records of Dr. Matthews, to be convinced of this from the very quality of tone in which they are sung. In all of them the sounds resemble howling more than singing, yet they are unmistakably musical in two very important particulars: (1) In their strongly marked rhythm. (2) In the unquestionably harmonic relations of the successive tones."

The limits of this article forbid following Professor Fillmore in his treatment of these two particular points, Rhythm and Harmonic melody, or to recount the evidence leading to his conclusion 'that the harmonic sense is the shaping, formative principle in folk melody.'

Of the many interesting points brought forward in this volume, only one or two can be indicated, and these are selected not so much to give the scope of the volume as to illustrate its wealth of suggestion.

In accounting for the limited number of arts practiced by the Navahoes, the author says: "In developing their blanket making to the highest point of Indian art, the women of this tribe have neglected other labors. The much ruder but allied Apaches, who know nothing of weaving woolen fabrics, make more baskets than the Navahoes, and make them in much greater variety of form, color and quality. The Navahoes buy most of their baskets and wicker water jars from other tribes. They would possibly lose the art of basketry altogether if they did not require certain kinds to be used in the rites, and only women of the tribe understand the special requirements of the rites." It would seem that special proficiency in the manufacture of some one article, while it may limit the development along other lines, leads to trade and the peaceful intercourse between different peoples.

In introducing the subject of poetry and music the author calls attention to the fact that for many years the most trusted account of the Navaho Indians was to be found in a letter published in the Smithsonian Report for 1855. The writer had lived three years in the heart of the Navaho country, and was aided in preparing this letter by an officer in the United States Army who had long commanded a post in the vicinity, both being men of unusual ability. From this letter the following statement is taken: "Of their religion little or nothing is known, as, indeed, all inquiries tend to show that they have none. 'The lack of tradition is a source of surprise. They have no knowledge of their origin or of the history of the tribe.' 'They have frequent gatherings for dancings.' 'Their singing is but a succession of grunts, and is anything but agreeable.' In spite of the evidence of these gentlemen, fifteen years ago when the author first found himself among the Navahoes he was not influenced in the least by the authority of this letter. He had not been many weeks with these Indians when he discovered that the dances referred to were religious ceremonials, vying 'in allegory, symbolism, and intricacy of ritual with the ceremonies of any people, ancient or modern.' The 'succession of grunts' reveal 'that besides improvised songs, in which the Navahoes are adepts, they have knowledge of thousands of significant songs—poems, as they might be called—which have been composed with care and handed down, for centuries perhaps, from teacher to pupil, from father to son, as a precious heritage, through the wide Navaho nation.' "

The author's rich gleaning in a field pronounced barren can be repeated elsewhere in the land, but, to achieve results like his, similar equipment is necessary. It is not enough, as the incident just quoted shows, 'to live in the vicinity' of a people; to report accurately upon them, one must have come so near to them and in such manner as to draw from willing lips their tribal lore.

It would be unjust to Dr. Matthews's work, and to the lesson it contains for us, not to call attention to the characteristic which is an important factor in making him a trustworthy authority in any field where he has studied,

his hearty recognition of the claims of a common humanity. This recognition makes him appreciate the seriousness of interpreting the men of one race to men of another race, and begets a fairness of presentation that lifts his work to a high standard of truthfulness. His manly conscientiousness is evident throughout the book in the choice of words, in the turn of a sentence, in the "testimony in favor of the Shamans, and the incidents related of Tall Chanter, Torlino and others; it is also noticeable in the illustrations of the book, particularly in the portraits, which, while characteristic, are without the brutal exaggerations of feature so painfully common in Indian pictures. While this may be regarded as the personal equation of the author, it nevertheless indicates certain qualities, the presence or absence of which in a field investigator helps or mars his work."

The contributions to ethnology offered in this volume are particularly timely, for the questions, "How have the tribes of North America been built up?" and "what have been the directive influences in determining their arts, cults and organization?" are of increasing importance, as the study of our native peoples passes beyond the initial stage. The student is under great obligations to the author for the perspicuous presentation of his material, due to his grasp of the subject, power of classification and concise statement, and his ability to rigorously exclude extraneous matter.

The excellent workmanship of the book—the type and illustrations, three being in colors—is worthy of the publishers, and reflects credit upon the Folk-Lore Society.

ALICE C. FLETCHER.

BOTANY OF THE AZORES.*

SINCE the publication of Hewett C. Watson's chapters on botany in Godman's Natural History of the Azores, published nearly thirty years ago, no important contributions have been made to the botany of this group of oceanic islands. The present paper, based on two summers spent in the islands, is a catalogue of all of the plants, cryptogamic as well as phanerogamic, heretofore recorded as Azorean, with a reasonable attempt at the exclusion of synonyms, especially in the higher groups. While in the phanerogams comparatively few species have been added to those previously recorded, the distribution by islands is indicated much more fully than ever before, and the list of Thallophytes very considerably increased. It is stated that, although the list of flowering plants and ferns is believed to be nearly complete, and perhaps relatively few additions to the lichens will be made, the fungi are still practically unstudied, and the algal flora, especially that of the wet sphagnum with which the highlands are usually covered, is likely to be very greatly increased by careful study. In the catalogue a reference is given, under each species, to places in which it has previously been mentioned as Azorean, and an adequate description and plate are cited. Where the latter has not been practicable, the species has been figured. In connection with this paper should also be noted Cardot's recent paper on the mosses of the Azores and of Madeira, previously mentioned in these columns.

A STATEMENT CONCERNING THE MARINE BIOLOGICAL LABORATORY AT WOOD'S HOLL, MASS.

THE undersigned wish to state to the public, and especially to those who have contributed to the support of the Marine Biological Laboratory, the circumstances which have resulted in their separation from the management of the institution of which they were recently trustees.

1. The Laboratory was founded by the Woman's Education Association, in cooperation with the Boston Society of Natural History at Annisquam in 1881, and in 1888 it was completely reorganized and changed into a corporation under the laws of Massasetts. Its affairs have been managed by a board of trustees, three of whom were members of the Woman's Education Association. All the members of the original board resided in or near Boston. A few years later the board was enlarged to take in representatives of universities in various States. The original board decided upon the location, scope and organization of the laboratory, bought the land at Wood's Holl, designed and erected the first building, selected and purchased the original equipment, and appointed Dr. Whitman director to administer the laboratory. The funds for the establishment of the institution came almost exclusively from Boston. During the following years additional land was bought, and five important additions to the buildings were made, for all of which the funds were secured through the exertions of the Boston trustees, with, however, a few lesser contributions from elsewhere. In 1896 another building was erected at a cost of $3,500, and of this

amount by far the larger part was raised outside of Boston and its connections. The total amount of money contributions is $41,029, of which about nine-tenths was secured through the Boston members of the board of trustees. To the list of these services to the laboratory must be added the establishment and maintenance of the large dining club, without which the laboratory could not have grown to its present size.

In consideration, then, of these facts, that the plan of providing both for instruction and for investigation, and the continued life of the laboratory, have hitherto depended primarily upon the efforts of the Boston trustees, may it not be claimed that they might reasonably have expected justice and consideration from those who alone had any direct advantage from their efforts.

2. Dr. Whitman was appointed Director and has ably carried out the original plans of the trustees, and though the general plan and scope of the Laboratory have remained unchanged from the start, Dr. Whitman has suggested and carried through valuable modifications and he has devoted his summers and other time to the Laboratory for nine years, and has served through the whole period without remuneration. Under these circumstances the trustees have always striven to meet Dr. Whitman's wishes in every practical way, and have repeatedly laid aside their own preferences and convictions in order to give the Director the fullest expression of their recognition of his services. There gradually arose, however, a serious divergence of views upon important points between Dr. Whitman, upon the one hand, and the trustees, as recorded by the votes and discussions of the board, on the other.

The first point related to the general policy of the Laboratory. A large majority of all the trustees who have ever attended a meeting were convinced that the wisest course was to plan at once a permanent building, with first-class equipment, and to endeavor to secure a permanent endowment. Dr. Whitman wished first to erect more temporary buildings, although the debt of the Laboratory was thereby increased. Out of deference to Dr. Whitman the Board yielded more than once, but last winter they showed a positive determination not to sanction the continuation of the policy.

The second point concerned the financial management. The trustees held that it was their duty to exercise an effective control of the finances, in accordance with their legal obligation under the act of incorporation, and, therefore, that they must regulate the general appropriations, such as those for salaries, for running expenses, etc. Dr. Whitman, on the contrary, apparently considered that the expenditures were to be regulated solely by him, and acted accordingly. He exceeded his appropriations for running expenses and spent money necessary for certain uses for an unauthorized purpose. The trustees adopted the most generous and lenient view possible of these occurrences, for they attributed them to Dr. Whitman's ignorance of the ordinary rules of financial administration, until the violations became so extreme that it was unavoidable to take prompt and efficient steps to protect the Laboratory.

The following instances illustrate the character of Dr. Whitman's financial standards. In his report for 1895, p. 28, he presents figures to show that each time the trustees acceded to his wish for a new building the earnings of the Laboratory increased faster than the expenses. But Dr. Whitman's statement of the expenses for five of the eight years was extremely incorrect,* as shown in the following table:

* It is to be regretted that the errors were not observed in time to withdraw them from publication.

Year.	Dr. Whitman's Figures.	Actual Figures.*
1888	$1320.	$2205.
1889	1554.	2377.
1890	2430.	3041.
1891	3498.	3346.
1892	4132.	4049.
1893	4264.	4110.
1894	4882.	6940.
1895	8010.	8474.

He failed also to note that with each new building, since 1891, the confidence in the Laboratory diminished and thereafter the gifts to the institution decreased.

Year.	New Building.	Gifts.
1888	(first)	$9926
1889	——	5400
1890	one	2984
1891	——	5875
1892	one	5113
1893	one	3613
1894	one	2977
1895	——	2368
1896	one	1122
1897	——	1651†

As an illustration of Dr. Whitman's views as to the finances of the Laboratory, he maintained that the last new building paid for itself because the rooms were occupied, but was unable to recognize that he had used the privilege of inviting guests to the Laboratory so liberally that if these workers, who paid nothing, had been dropped, the extra rooms provided in the new building would have been unnecessary. The charge for an investigator's room is $100. The number of non-paying guests invited by Dr. Whitman was fourteen in 1896 and eleven in 1897.

Again, last winter the Laboratory was in debt, a debt which the trustees were obliged to meet. The Assistant Director held certain sums which he had collected from sales of supplies. The Treasurer called in these sums, but was met by a refusal because the Assistant Director had been told by Dr. Whitman to retain the money, subject to his order.

Other illustrations of the embarrassments caused by Dr. Whitman in the financial management of the Laboratory might be enumerated.

The lack of financial ability, demonstrated by the Director, rendered it in the judgment of the Trustees, imperative to protect the interests of the Laboratory. The Trustees therefore appointed a trained business man as Bursar, who received orders to pay all bills approved by Dr. Whitman, up to the limit of the appropriations. The Bursar proved very efficient and satisfactory, and furnished the trustees with clear and definite summaries of the receipts and expenditures during the summer.

3. The trustees as a body were desirous of making the Laboratory a truly national institution, while Dr. Whitman apparently wished to convert it into an organization under his own exclusive control. The trustees decided to insist upon their authority as the fulfilment of a trust confided to them by the subscribers to the funds of the Laboratory.

At the close of the session of 1896 the trustees were confronted by a deficit of about $1,500,* according to the written official statement of the Treasurer. This deficit was due to two causes: *first*, Dr. Whitman had greatly exceeded the income at his disposal; *second*, he used nearly $400 necessary for covering the running expenses, and spent it for an unauthorized purpose, disregarding a vote of the trustees.

He justified this act by stating, afterwards, that Mr. Nunn had promised this sum for that use. To offset this deficiency the trustees had only certain expected fees

* Compiled from the Treasurer's Reports. As certain items, such as postage, printing, etc., which represent regular annual expenses are not included, several of these amounts are less than they should be.

† Includes Mr. Nunn's payment of $398.

*The exact amount could not be given, as certain bills had not been sent in.

for the past season, but these belated fees, amounting last year to several hundred dollars, it has been the custom to reserve to cover the expenses of opening the Laboratory the following season. Under these conditions it was impossible to plan to open the Laboratory until funds were secured to cover the deficit, and Dr. Whitman was so informed. The Laboratory had, in addition, a debt of about $5,500. After several months the $398.59 used by Dr. Whitman was restored to the treasury by a payment made for that purpose by Mr. Nunn. The trustees applied all the fees they could collect to cover the deficit and finally raised in Boston $1,144, and thereupon immediately made public announcement of the opening of the Laboratory.

Dr. Whitman, who was the cause of these difficulties, and therefore of the delay in issuing the announcement for 1897, blamed the trustees not only for their conservatism, but also for that delay and for the appointment of a Bursar, which his deficiencies had rendered indispensable.

A written offer was received in April, 1897, from Mr. L. L. Nunn, of Telluride, Colorado, a brother-in-law of the Director and one of the trustees of the Laboratory since January, 1896. This offer substantially was as follows:

Mr. Nunn offered to pay the deficit in the running expenses at Wood's Holl for the season of 1897, after devoting towards the payment of such expenses all proceeds obtained from the operations at Wood's Holl. These running expenses did not include insurance, interest on the debt, or the expenses of the Treasurer's office. The offer was made upon the condition that Dr. Whitman directed the Laboratory in accordance with his best judgment and that Mr. Allen, 'or some other person acceptable to me' (Mr. Nunn's words), be employed as Assistant Treasurer at Wood's Holl. Mr. Nunn made himself responsible only for expenses incurred with consent of said Assistant Treasurer or himself.

It is to be noted that Mr. Nunn offered an uncertain amount and made no promise of subsequent assistance, but did state expressly to the trustees, at a meeting, that no large gift could be expected from him. As the acceptance of this offer was conditional on the discharge of the Bursar already engaged by the trustees, and as the trustees did not consider it wise to relinquish all responsibility, even for a limited time, to one of their number, Mr. Nunn's proposition was declined by a recorded vote of nine to one, and the decision was communicated to him by the Treasurer in the following terms:

April 15th, 1897.

L. L. NUNN, Esq.,

Dear Sir:

I have your letter of April 9th from Provo, Utah, enclosing draft of your offer to the Trustees of the Marine Biological Laboratory.

The Trustees, after giving your generous offer careful consideration since your visit to Boston, and after a meeting at which the subject was fully discussed, were with one exception of the opinion that it would not be compatible with their duties as Trustees of the Laboratory, to resign into the hands of Dr. Whitman the entire direction of its policy, even though guaranteed by you against any financial loss during the coming season.

Your first letter and draft were never received by me; I presume they miscarried in the mail, and your second letter did not arrive until after the meeting, but I do not find anything in it which materially differed from the proposition as originally made to the Trustees by word of mouth. I shall transmit your letter and offer to the Secretary, in order that they may be submitted to the Trustees at their next meeting, but I think we may regard the matter as definitely settled without awaiting further action.

Personally, I believe that the decision of the Trustees was a necessary one; at the same time, I confess to great reluctance in foregoing on behalf of the Laboratory your generous assistance, and we must certainly all be very grateful to you for the interest you have taken in our project.

Yours truly,

LAURENCE MINOT.

4. The customary summer meeting of the

board of trustees was held at Wood's Holl on August 6, 1897. At this meeting only a small attendance is expected, as it is known that many members are usually absent on expeditions or vacations, and, accordingly, until this year only routine business had been transacted at this meeting. Before this meeting began, Dr. Whitman stated, deliberately, to the Acting President in response to a question, that there was no important new business to be brought forward. After the hour of the meeting the four members of the board who had come from Boston to attend were kept waiting half an hour for the arrival of the other members who were then at Wood's Holl, although it was known that most of the Boston trustees must return by the last train in two hours. On the motion of Dr. E. G. Gardiner some 150 new members of the corporation were elected, most of them students at the Laboratory. Without this election it is doubtful if the subsequent plans could have been carried through. After all the business known to the President and Secretary had been transacted, Dr. Whitman introduced an extended discussion on some matters of the past (about which no action was possible). Almost immediately thereafter it became necessary for three members to leave to take the last train to Boston, and a protest against continuing the meeting was made but was overridden. The meeting was continued by Dr. Whitman, Dr. E. G. Gardiner, Professor J. P. McMurrich, Professor S. F. Clarke and the Secretary, who remained. The proposition to hold the annual meeting at Wood's Holl, a piece of important new business, for which there had previously been ample opportunity was then brought forward, and the following votes were passed, the Secretary voting in the negative in each case. The Secretary also made strong protests against passing so revolutionary measures after the Acting President and two trustees had left the meeting.

Voted on the motion of Dr. E. G. Gardiner: That the clerk be directed to call a special meeting of the corporation to consider the advisability of changing the by-laws, the meeting to be held at the Parker House, Boston, on August 16th.

Voted: That the temporary chairman (Professor McMurrich) appoint a committee of three to formulate the changes in the by-laws.

The committee was constituted with Dr. Gardiner, chairman; Dr. Whitman and Professor Clarke.

The purpose of the proposed changes was to have the annual meetings of the corporation held at Wood's Holl, to change the board of trustees from a body practically self-perpetuating to an elective body, and to place the control of the Laboratory in new hands.

We consider the action taken entirely unjustifiable, owing to the methods employed. There are also special reasons which made it unsuitable for Dr. Whitman and for Dr. Gardiner and Professor McMurrich to pursue the course taken.

In his Report for 1895, p. 47, Dr. Whitman says: "It still remains possible for a minority of four to hold meetings at convenience in Boston and regulate the affairs of the Laboratory, and that, too, in the absence of every one familiar with the needs. It makes no difference whether this has or has not been done; the possibility of its being done is what jeopardizes vital interests of the Laboratory."

We call attention to the fact that Dr. Whitman, aided by Messrs. Gardiner, McMurrich and Clarke, is the first and only person who has profited by the possibility he so emphatically condemned, and that, by utilizing it, he and his three supporters succeeded in setting aside the expressed wishes of the board of trustees, and in changing

the national character of the Laboratory.

In August 1895, the trustees appointed a committee 'to take into consideration a reorganization of the governing body.' In 1896 Dr. Gardiner was made chairman of this committee, of which Professor McMurrich was also a member. A resolve proposing certain changes in the mode of government of the Laboratory, introduced by one of the trustees, was referred to the committee.

We regret that the committee, in spite of many repeated requests to its chairman, made no report, and that Dr. Gardiner and Professor McMurrich, instead of acting in consultation with their fellow trustees, adopted a plan to reorganize the government of the Laboratory by other means.

5. The special meeting was duly held at the Parker House, Boston, on August 16th. A large attendance from Wood's Holl was secured, it is said, by hiring a special car and offering to pay the fares of the members of the Corporation, many of whom had been elected only a few days before. It was proposed by some of the Boston trustees to ask for a hearing before this meeting, but the gathering seemed to them so evidently packed that they considered any attempt to obtain a hearing useless. The proposed changes in the by-laws were carried through. The most important one of these is that which fixes the annual meeting for the summer at Wood's Holl. This change seems well calculated to enable the Director to maintain practically control over the Corporation. Other changes made are likely also to favor this result.

The newly appointed annual meeting of the Corporation was held at Wood's Holl on August 24th. A new board of trustees was elected and five of the Boston trustees were dropped. The Boston trustees could make no defense, because they had never heard any accusations and had no information until the meeting of their projected exclusion. Moreover, nearly all the undersigned were necessarily absent from that meeting.

Although without the labors of the five trustees who were dropped from the board the Laboratory might never have existed, and although Dr. Whitman was under many obligations to them, they were ejected from the board by means which can only be considered underhand and dishonorable. We believe that such a policy must injure the Laboratory seriously and we are unable to give it support or approval.

The main points of this statement are as follows:

1. The recognition of the scientific ability of the Director, his devotion and services to the Laboratory.

2. The utter lack of sound financial standards shown by the Director.

3. The dishonorableness of the methods employed to reorganize the government of the Laboratory.

4. The ignorance of the facts on the part of the members of the Corporation present at the meetings of August 16th and 24th, which helped to make this reorganization possible.

THE JESUP EXPEDITION TO THE NORTH PACIFIC COAST.

IT will be remembered that in the spring of this year Mr. Morris K. Jesup, President of the American Museum of Natural History, provided the means for a thorough ethnological investigation of the northern portions of the Pacific coasts of Asia and North America.

It was decided to begin field work on the American coast, and in May a party consisting of Dr. Franz Boas, Dr. Livingston Farrand and Mr. Harlan I. Smith left New York in order to carry on anthropological investigations in British Columbia. In previous years the Committee of the British Association for the Advancement of Science appointed for studying the tribes of northwestern Canada had carried on investigations in British Columbia. This committee was about to conclude its field work. Since the territory in which the operations of the Jesup Expedition are to be conducted embraces the field of work of the committee, it seemed desirable to have the operations of both parties conducted on a common plan. The committee was desirous of completing its anthropometric survey of British Columbia and to obtain information on the Tinneh tribes of the interior of that Province. This work was entrusted to the party of the Jesup Expedition and has been done by Dr. Farrand and Dr. Boas.

During the past season the work of the Jesup Expedition was directed mainly to an exploration of the prehistoric remains of British Columbia, to a study of the Bella Coola Indians and of the northern Kwakiutl Indians. A special study of the art of the Indians of the North Pacific coast was included in the plan of work. In all these directions good progress has been made. The work was divided in the following way. Mr. Smith was charged with the archæological investigations; Dr. Boas and Dr. Farrand collected anthropometrical data, and Dr. Farrand undertook the study of the Chilcotin for the British Association for the Advancement of Science, and later on carried on inquiries on the sociology of the northern Kwakiutl. Dr. Boas investigated the Bella Coola Indians and later on studied the art of the northern tribes. He concluded his work with a study of the language of the northern Kwakiutl. In British Columbia Mr. James Teit and Mr. George Hunt joined the party, the former to assist in work on the Thompson River Indians, the latter to assist in work among the Kwakiutl tribes. Mr. Teit has promised to furnish for the expedition a description of the Thompson River Indians. Mr. Hunt's services were of the greatest value on account of his intimate knowledge of the Kwakiutl language and of the customs of the people.

The result of this summer's work may be summarized as follows: Mr. Smith investigated archæological remains at four points: at Kamloops, Spence's Bridge, at the famous burial ground at Lytton and at Port Hammond.

The remains found at Kamloops belong to a number of periods preceding contact with the whites. In all the sites objects made of shell, copper, bone and stone were found. The general shape of these objects suggest that the people using them were the immediate ancestors of the tribes inhabiting these regions at the present day. Most of the material was found buried in shifting sand, owing to which fact the original order has been much disturbed.

The remains found at Lytton were of a character similar to those found at Kamloops. While a thorough investigation of the finds may show that there existed differences in the cultures of these regions, the general characteristics of the material are much alike. In both places the

finds were made in ancient burials or in caches.

At Port Hammond Mr. Smith investigated a number of shell heaps. These have a thickness of $4\frac{1}{2}$ feet or less, and the remains found in the heaps were ascertained to be not intrusive. A number of skeletons and well-preserved artefacts were found. There is no difference in the character of the objects found in the lowest layers and in the higher layers. Judging by the size of trees growing on the shell heaps, these sites must have been deserted for a considerable length of time, but there is no evidence pointing to a very great antiquity of the remains. Further conclusions cannot be drawn until the material obtained in these localities has been subjected to a thorough investigation.

Dr. Boas' investigations on the Bella Coola gave some results of considerable interest. Previous inquiries had shown that the Bella Coola possess a highly developed mythology. Further studies have shown that they are the only tribe on the North Pacific coast that have systematized their mythology. While among them we find most of the elements of the mythologies of the neighboring tribes, this material has been so elaborated that instead of a multitude of spirits we find a number of deities, each with its proper functions. The Bella Coola believe that there are five worlds, an upper heaven over which rules the supreme goddess Qamaits. The lower heaven is the home of a number of deities, the most powerful of whom is the sun, called by the Bella Coola 'Our Father' and 'The Sacred One.' The deities reside in a house located in the zenith. It is called 'House of Myths.' The thoughts of these deities are put into action by four brothers, who live in a separate room in the rear of the house. Here also reside ten brothers, to whose care the winter ceremonial is entrusted. The sun walks from east to west every day. In the east in heaven sits the 'Bear of Heaven,' watching the 'Place of Dawn.' On the west is the pillar, which prevents the sun from passing into the lower world. Twenty-four watchmen are appointed to look after the sky and to keep it in good order. Three others fly around the sun watching his course. At winter solstice and summer solstice are stationed two watchmen, whose duty it is to prevent his tarrying at those places. Our own world—the earth—is an island in the ocean. In the far east a god is sitting, who holds a strong bar in both his hands. Stone ropes are tied to this bar by means of which the earth is held in place. In the far west is the salmon land. The world underneath ours is that of the ghosts. Everything there is the reverse of what it is here. The ghosts walk on their heads. When it is winter here it is summer there, When it is daylight here it is night-time there. The deceased may return to life by being born again. When a ghost dies his soul goes to the lowest world, from which there is no return. The year is divided into two periods. In summer the 'canoe of the salmon' stays in our world. In October it returns to the salmon country and at the same moment the 'canoe of the winter ceremonial' arrives. As soon as this canoe reaches the banks of the river the whole tribe embark and are conveyed to the 'House of Myths,' in heaven. At the same time the female spirit of the winter ceremonial, of which there is one for each village, leaves her abode in the mountains and shows herself. At the time of the winter solstice the 'canoe of the winter ceremonial' returns and the 'canoe of the salmon' arrives from the salmon country. These mythological ideas are the foundation of the calendar of the people, which has twelve months, two indefinite periods around the solstices and five months between the solstices.

The traditions of the Bella Coola are, to a great extent, totemic. Only members of the clan have the right to relate their traditions and to use the carvings based on their traditions. This has led to a system of endogamic marriage which was intended to prevent the acquisition of clan rights by other clans. This system is breaking down under the influence of the Kwakiutl system of exogamic marriage.

Investigations on the art of the Indians were mainly based on the consideration that the process of conventionalization will probably progress the farther the more difficult the treatment of the surface to be decorated. It seemed that no surface offers greater difficulties than the human face, and for this reason a considerable number of facial paintings were collected. The results of this collection met the expectations, since a number of highly conventionalized designs, some of purely geometrical character, were obtained. In addition to these a number of designs from house fronts and from edges of blankets were obtained.

The studies on the languages of the Kwakiutl Indians cannot very well be summarized in a few words. Texts were obtained in two dialects, the Awikyenok and the Kwakiutl proper, which will probably form a satisfactory basis for a full treatment of these dialects.

On account of the difficulties encountered in previous work on the physical characteristics of the tribes, it was deemed desirable to base the work on better material. Previous collections consisted of measurements and brief descriptive notes of types. These latter proved to be very unsatisfactory on account of the vagueness of the terms employed. Photographs obviate this difficulty to a certain extent, but not adequately, owing to the effects of perspective forshortening. For this reason it was deemed desirable to try if the subject can be treated more advantageously by means of a systematic collection of plaster casts, which will facilitate comparison. This seemed particularly important, since the study of the physical types of the coast of the North Pacific Ocean must form one of the most important subjects of investigation of the Jesup Expedition. A series of one hundred casts have been obtained, representing four distinct types of British Columbia. The collection will be subjected to a critical examination in order to ascertain the usefulness of the method of investigation. The collection was made by all the members of the party. Each cast is accompanied by four photographs of the subject on a scale of about 1:5, front view, two profiles and one half profile. These photographs were taken by Mr. Harlan I. Smith.

Dr. Farrand, in his work among the Chilcotin, obtained considerable ethnological information, both as regards mythology and general customs. In both these fields striking evidence of the influence of contact with neighboring tribes was found ; thus in certain myths details of clearly coast origin, along with those bearing unmistakable marks of the interior, were found grafted upon otherwise independent Chilcotin stories. In social organization the Chilcotin, unlike the Tinneh tribes immediately to the north of them, show few signs of coast influence. No traces of clan organization were seen. Recognized relationship was regarded as a bar to marriage, but this recognition was apparently not carried further than cousins of the first degree. The general condition and habits of the tribe have been greatly changed during the last thirty years, owing to the establishment of reservations upon which most of the people have been settled who thus abandoned the wandering life to which they were formerly accustomed. A few families

still decline to come in to the reservations and keep up their old semi-nomadic life in the mountains.

As to the social organization of the Heiltsuk it was found that the tribe contains four clans—the eagle, wolf, raven and killer whale. There is nothing corresponding to the phratries of tribes farther north, but the individual clans are strictly exogamous, and marriage is also forbidden with members of corresponding clans in certain other tribes. Descent is mixed, maternal and paternal, but preference is shown for the clan of the mother. In the case of a single child it almost invariably takes the maternal clan. There were formerly three social classes—nobility, common people and slaves. The nobility or chiefs were of different ranks, higher position being obtained by means of the potlatch. A member of the lower classes, however, could never obtain nobility.

A very considerable number of specimens were collected by the expedition which will materially increase the scientific value of the collections from the North Pacific coast in the American Museum of Natural History. The new material consists mainly of archæological collections from Kamloops, Lytton and Port Hammond; an ethnological collection from Spence's Bridge, another one from Chilcotin Valley. From the northern part of the coast a very full collection of masks and carvings illustrating mythology of the Bella Coola was obtained. Another collection illustrates the arts and ceremonials of the Kwakiutl and of the Nootka. Finally the large collection of casts and photographs of Indians must be mentioned.

Ethnology is deeply indebted to Dr. Jesup for inaugurating this important investigation, which, we may hope, will help to settle finally a number of the most difficult problems regarding the early history of mankind.

*EXPERIMENTAL MORPHOLOGY.**

IN looking at the progress which has been made in the study of plant morphology I have been as much impressed with the different attitudes of mind toward the subject during the past 150 years as by the advance which has taken place in methods of study and the important acquisitions to botanical science. These different view points have coincided to some extent with distinct periods of time. What Sachs in his 'History of Botany' calls the 'New Morphology' was ushered in near the middle of the present century by Von Mohl's researches in anatomy, by Naegeli's investigation of the cell and Schleiden's history of the development of the flower. The leading idea in the study of morphology during this period was the inductive method for the purpose of discerning fundamental principles and laws, not simply the establishment of individual facts, which was especially characteristic of the earlier period when the dogma of the constancy of species prevailed.

The work of the 'herbalists' had paved the way for the more logical study of plant members by increasing a knowledge of species, though their work speedily degenerated into mere collections of material and tabulations of species with inadequate descriptions. Later the advocates of metamorphosis and spiral growth had given an impetus more to the study of nature, though diluted with much poetry and too largely subservient to the imagination or idealistic notions.

But it was reserved for Hoffmeister,† whose work followed within three decades of the beginnings of this period, to add to the

*Address of the Vice-President before Section G—Botany—of the American Association for the Advancement of Science, Detroit, 1897.

† Bibliographical details will be appended when the address is published in the Proceedings of the Association.

inductive method of research as now laid down the comparative method, and extending his researches down into the Pteridophyta and Bryophyta, he not only established for these groups facts in sexuality which Camerarius and Robert Brown had done for the Spermatophyta, but he did it in a far superior manner. He thus laid the foundation for our present conceptions of the comparative morphology of plants. Naegeli's investigations of the cell had emphasized the importance of its study in development and now the relation of cell growth to the form of plant members was carried to a high degree, and an attempt was made to show how dependent the form of the plant was on the growth of the apical cell in the Pteridophyta and Bryophyta, though later researches have modified this view, and how necessary a knowledge of the sequence of cell division was to an understanding of homologies and relationships. Thus in developmental and comparative studies morphology has been placed on a broader and more natural basis, and the homologies and relationships of organs between the lower and higher plants are better understood.

But the growth of comparative morphology has been accompanied by the interpretation of structures usually from a teleological standpoint, and in many cases with the innate propensity of the mind to look at nature in the light of the old idealistic theories of metamorphosis.

I wish now to enquire if we have not recently entered upon a new period in our study of comparative morphology. There are many important questions on which comparative studies of development under natural or normal conditions alone cannot afford a sufficient number of data. We are constantly confronted with the problems of the interpretation of structure and form, not only as to how it stands in relation to structures in other plants which we deal with in comparative morphology, but the meaning of the structure or form itself, and in relation to the other structures of the organism, in relation to the environment and in relation to the past. This must be met by an enquiry on our part as to why the structure or form is what it is, and what are the conditions which influence it. This we are accustomed to do by *experiment*, and it begins to appear that our final judgments upon many questions of morphology, especially those which relate to variation, homology, etc., must be formed after the evidence is obtained in this higher trial court, that of *experimental morphology*. While experimental morphology as a designation of one branch of research in plants, or as a distinct and important field of study, is not yet fully taken cognizance of by botanists, we have only to consult our recent literature to find evidence that this great and little explored field has already been entered upon.

Experimental methods of research in the study of plants have been in vogue for some time, but chiefly by plant physiologists and largely from the standpoint of the physical and chemical activities of the plant, as well as those phases of nutrition and irritability, and of histologic structure, which relate largely to the life processes of the plants, and in which the physiologist is therefore mainly interested. In recent years there has been a tendency in physiological research to limit the special scope of these investigations to those subjects of a physical and chemical nature. At the same time the study of the structure and behavior of protoplasm is coming to be regarded as a morphological one, and while experimental methods of research as applied to the morphology of protoplasm and the cell is comparatively new there is already a considerable literature on the subject, even from the side of plant organisms (Davenport, '97). While certain of the

phenomena of irritability and growth are closely related to the physics of plant life, they are essentially morphologic, and it is here especially that we have a voluminous literature based strictly on the inductions gained by experimentation, and for which we have chiefly to thank the plant physiologists.

If we were to write the full history of experimental morphology in its broadest aspects we could not omit those important experimental researches on the lower plants in determining the ontogeny of polymorphic species among the algæ and fungi which were begun so ably by DeBary, Tulasne, Pringsheim and others and carried on by a host of European and American botanists. The tone which these investigations gave to taxonomic botany has been felt in the study of the higher plants, by using to some extent the opportunities at botanic gardens, where plants of a group may be grown under similar conditions for comparison, and in the establishment of alpine, subalpine and tropical stations for the purpose of studying the influence of climate on the form and variations of plants, and in studying the effect of varying external conditions.

While experimental morphology in its broadest sense also includes in its domain cellular morphology and the changes resulting from the directive or taxic forces accompanying growth, it is not these phases of morphology with which I wish to deal here.

The question is rather that of experimental morphology as applied to the interpretation of the modes of progress followed by members and organs in attaining morphologic individuality, in the tracing of homologies, in the relation of members associated by antagonistic or correlative forces, the dependence of diversity of function in homologous members on external and internal forces, as well as the causes which determine the character of certain paternal or maternal structures. I shall deal more especially with the experimental evidence touching the relation of the members of the plant which has been represented under the concept of the leaf as expressed in the metamorphosis theory of the idealistic morphology. The poetry and mystery of the plant world, which was so beautifully set forth in the writings of Goethe and A. Braun, are interesting and entrancing, and the poetic communication with nature is elevating to our ethical and spiritual natures. But fancy or poetry cannot guide us safely to the court of inquiry. We must sometimes lay these instincts aside and deal with nature in a cold, experimental, calculating spirit.

The beginnings of experimental morphology were made about one century ago, when Knight, celebrated also for the impulse which he gave to experimental physiology, performed some very simple experiments on the potato plant. The underground shoots and tubers had been called roots until Hunter (77) pointed out the fact that they were similar to stems. Knight tested the matter by experiment, and demonstrated that the tubers and undergound stems could be made grow into aërial leafy shoots. This he regarded as indicating a compensation of growth, and he thought farther that a compensation of growth could be shown to exist between the production of tubers and flowers on the potato plant. He reasoned that by the prevention of the development of the tubers the plant might be made to bloom. An early sort of potato was selected, one which rarely or never set flowers, and the shoots were potted with the earth well heaped up into a mound around the end of the shoot. When growth was well started the soil was washed away from the shoot and the upper part of the roots so that the plant was only connected with the soil by the roots. The

tubers were prevented from growing and numbers of flowers were formed. This result he also looked upon as indicating a compensation of growth between the flowers and tubers. While we recognize Knight's experiments as of great importance, yet he erred in his interpretation of the results of this supposed correlation between the tubers and flowers, as Vöchting has shown. By repeating Knight's experiment, and also by growing shoots so that tubers would be prevented from developing, while at the same time the roots would be protected, flowers were obtained in the first case while they were not in the second, so that the compensation of growth, or correlation of growth, here exists between the vegetative portion of the plant and the flowers instead of between the production of tubers and flowers as Knight supposed.

The theory of metamorphosis as expressed by Goethe and A. Braun ('51) and applied to the leaf regarded the leaf as a *concept* or *idea*. As Goebel ('80) points out, Braun did not look upon any one form as the typical one which through transformation had developed the various leaf forms, but each one represented a wave in the march of the successive billows of a metamorphosis, the shoot manifesting successive repetitions or renewals of growth each season, presenting in order the 'niederblätter, laubblätter, hochblätter, kelchblätter, blumenblätter, staubblätter, fruchtblätter. Though it had been since suggested from time to time, as Goebel ('80) remarks, that the foliage leaf must be regarded as the original one from which all the other forms had arisen (though at that time Goebel did not think this the correct view), no research, he says, had been carried on, not even in a single case to determine this point. Goebel plainly showed in the case of *Prunus padus* that axillary buds which under normal conditions were formed one year with several bud scales could be made by artificial treatment to develop during the first year. This he accomplished by removing all the leaves from small trees in April, and in some cases also cutting away the terminal shoot. In these cases the axillary shoot, instead of developing a bud which remained dormant for one year as in normal cases, at once began to grow and developed well-formed shoots. Instead of the usual number of bud scales, there were first two stipule-like outgrowths, and then fully expanded leaves were formed, so that in this case, he says, the metamorphosis of the leaf to bud scales was prevented. For this relation of bud scales to foliage leaves Goebel proposed the term 'correlation of growth' ('80). In the case of *Vicia faba* removal of the lamina of the leaf of seedlings when it was very young caused the stipules to attain a large size and to perform the function of the assimilating leaf. He here points out that experimentation aids us in interpreting certain morphological phenomena which otherwise might remain obscure. He cites the occasional occurrence (Moquin-Tandon) in the open of enlarged stipules of this plant which his experiment aids in interpreting. In the case of *Lathyrus aphaca* the stipules are large and leaf-like, while the part which corresponds to the lamina of the leaf is in the form of a tendril, the correlation processes here having brought about the enlargement of the stipules as the lamina of the leaf became adapted to another function. Kronfeld ('86, '87) repeated some of Goebel's experiments, obtaining the same results, and extended them to other plants (*Pirus malus* and *Pisum sativum*), while negative results attended some other experiments. Hildebrand, in some experiments on seedlings and cuttings, found that external influences affected the leaves, and in some cases, where the cotyledons were cut, foliage leaves appeared in place of the usual bud scales, and in *Oxalis rubella* removal of the

foliage leaf, which appears after the cotyledons, caused the first of the bulb scales, which normally appear following the foliage leaf, to expand into a foliage leaf.

In some experiments on the influence of light on the form of the leaves Goebel ('96) has obtained some interesting results. Plants of *Campanula rotundifolia* were used. In this species the lower leaves are petioled and possess broadly expanded, heart-shaped laminæ, while the upper leaves are narrow and sessile, with intergrading forms. Plants in different stages of growth were placed in a poorly-lighted room. Young plants which had only the round leaves under these conditions continued to develop only this form of leaf, while older plants which had both kinds of leaves when the experiment was started now developed on the new growth of the shoot the round-leaved form. In the case of plants on which the flower shoot had already developed, side shoots with the round leaves were formed. Excluding the possibility of other conditions having an influence here, the changes in the form of the leaves has been shown to be due to a varying intensity of light. The situation of the plants in the open favor this view, since the leaves near the ground in these places are not so well lighted as the leaves higher up on the stem. In this case the effect of dampness is not taken into account by the experimenter, and, since dampness does have an influence on the size of the leaf, it would seem that it might be at least one of the factors here. An attempt was now made to prevent the development of the round leaves on the young seedlings. For this purpose the germinating seeds were kept under the influence of strong and continuous lighting. The round leaves were nevertheless developed in the early stage, an indication that this form of the leaf on the seedling has become fixed and is hereditary. Hering ('96) found that enclosing the larger cotyledon of *Streptocarpus* in a plaster cast, so as to check the growth, the smaller and usually fugacious one grew to the size of the larger one, provided the experiment was started before the small one was too old. Amputation of the large cotyledon gave the same results.

Other experimenters have directed their attention to the effect of light and gravity on the arrangement of the leaves on the stem, as well as the effect of light on the length of the petioles and breadth of the lamina. Among these may be mentioned the work of Weisse ('95), Rosenvinge ('94), and others.

Goebel has shown experimentally that dampness is also one of the external influences which can change the character of xerophyllous leaves. A New Zealand species of *Veronica* of xerophyllous habit and scaly appressed leaves in the seedling stage has spreading leaves with a broad lamina. Older plants can be forced into this condition in which the leaves are expanded by growing them in a moist vessel ('96). Gain, Askenasy and others have shown that dampness or dryness has an important influence in determining the character of the leaves.

The results of the experiments in showing the relation of the leaf to the bud scales Goebel regards as evidence that the foliage leaf is the original form of the two, and that the bud scale is a modification of it.

Treub ('72) conducted some interesting experiments for the purpose of determining the homology of the pappus of the Compositæ. Gall-insects were employed to stimulate the pappus of *Hieracium umbellatum*, and it was made to grow into a normal calyx with five lobes. (A recent letter from Professor Treub states that he later repeated these experiments with other species of Compositæ with like results, but the work was not published.) Kny ('94) found in seedlings and cuttings which he experimented with that, while there was still

stored food available for the roots and shoots, there was little, if any, dependence of one upon the other. Hering ('96) comes to somewhat different conclusions as a result of his experiments, finding that in some cases there was a slight increase of growth, while in others growth of the one was reciprocally retarded when the other was checked in development. Numerous cases of horticultural practice in pollination of fruits show that the form and size of the fruit and of the adjacent parts, as well as the longer or shorter period of existence of the floral envelopes, can be influenced by pollination.

The investigations carried on by Klebs ('96) in the conjugation of *Spirogyra* suggest how experimentation of this kind may be utilized to determine questions which in special cases cannot be arrived at easily by direct investigation. If threads of *Spirogyra varians* which are ready for conjugation are brought into a (0.5%) solution of agar-agar, in such a way that nearly parallel threads lie at a varying distance in their windings, where they are within certain limits, the conjugation tubes are developed and the zygospores are formed; but where the threads lie at too great a distance for the influence to be exerted, the cells remain sterile, and no conjugation tubes are developed. If, now, these threads be brought into a nutrient solution, these cells, which were compelled to remain sterile, grow and develop into new threads, *i. e.*, they take on the vegetative, though they are fully prepared for the sexual function. Strasburger ('97) has pointed out that this may be taken as excluding the possibility of there being a reducing division of the chromosomes during the maturing of the sexual cells, a process which takes place in animals, and that the behavior of *Spirogyra* in this respect agrees with what is known to take place in the higher plants, viz., that the reduction process is not one which is concerned in the maturity of the gametes. The same could be said of *Polyphagus*, in which Nowakowski ('78) found that before the zygospore was completely formed the protoplasm moved out and formed a new sporangium.

In the case of *Protosiphon botryoides* Klebs was also able to compel the parthenogenetic development of the motile gametes, and the same thing was observed in the case of the gametes of *Ulothrix*. If we are justified in interpreting this phenomenon as Strasburger suggests, the evidence which Raciborski ('96) gives as a result of his experiments with *Basidiobolus ranarum* would support the idea that there is no reducing division in the chromosomes before the formation of the nuclei of the gametes. Raciborski found that in the case of the young zygospores of this plant, in old nutrient medium where the fusion of the plasma contents had taken place, but before the nuclei had fused, if they were placed in a fresh nutrient medium the fusion of the nuclei was prevented, and vegetative growth took place, forming a hypha which possessed two nuclei, the paternal one and the maternal one. Raciborski interprets Eidam's ('87) study of the nuclear division prior to the copulation of the gametes as showing that the reducing division takes places here as in the maturation of the sexual cells of animals, and looks upon the premature germination of the zygospore as showing that a paternal and maternal nucleus possesses the full peculiarities of a normal vegetative one. However, we are not justified in claiming a reducing division for the nuclei preceding the formation of the gametes in *Basidiobolus* from the work of Eidam, since he was not able to obtain sufficiently clear figures of the division to determine definitely how many divisions took place, to say nothing of the lack of definite information as to the number of chromosomes. Fairchild ('96)

has recently studied more carefully the nuclear division, but on account of the large number of the chromosomes was not able to determine whether or not a reduction takes place. He points out, as others have done, the similarity in the process of the formation of the conjugating cells of *Basidiobolus* and *Mougeotia* among the *Mesocarpeæ*, and to these there might be added the case of *Sirogonium* in which the paternal cell just prior to copulation undergoes division. The division of the copulation cell in *Basidiobolus*, *Mougeotia*, *Sirogonium*, etc., suggest at least some sort of preparatory act, but whether this is for the purpose of a quantitative reduction of the kinoplasm, as Strasburger thinks sometimes takes place, or is a real reduction in the number of the chromosomes, must be determined by further study, so that the bearing of these experiments on the question of a reducing division must for the time be held in reserve.

One of the very interesting fields for experimental investigation is that of the correlation processes which govern the morphology of the sporophylls (stamens and pistils) of the Spermatophyta. One of the controlling influences seems to be that of nutrition, and in this respect there is some comparison to be made with the correlative processes which govern the determination of sex in plants.

Among the ferns and some others of the Pteridophyta a number of experiments have been carried on by Prantl, Bauke, Heim ('96), Buchtien ('87) and others to determine the conditions which influence the development of antheridia and archegonia. Prantl found that in prothallia of the ferns grown in solutions lacking nitrogen there was no meristem and consequently no archegonia, while antheridia were developed, but if the prothallia were changed to solutions containing nitrogen, meristem and archegonia were developed. All the experiments agree in respect to nutrition; with scanty nutrition antheridia only were developed, while with abundant nutriment archegonia were also developed. Heim studied the influence of light and found that fern prothallia grow best with light of 20%–25%. Exclusion of the ultra violet rays does not affect the development of the sexual organs. He argues from this that the ultra violet rays are not concerned in the elaboration of the material for flower production as Sachs had suggested. In yellow light the prothallia grew little in breadth; they also grew upward, so that few of the rhizoids could reach the substratum. Antheridia were here very numerous. After seven months these prothallia were changed to normal light, and in four months afterward archegonia were developed.

Among the algæ Klebs ('96) has experimented especially with *Vaucheria*, such species as *V. repens* and *V. ornithocephala*, where the antheridia and oogonia are developed near each other on the same thread. With weak light, especially artificial light, the oogonium begins first to degenerate. He never succeeded in suppressing the antheridia and at the same time in producing oogonia.

High temperature, low air pressure or weak light tend to suppress the oogonia, and at the same time the antheridia may increase, so that the number in a group is quite large, while the oogonium degenerates or develops vegetatively. Klebs concludes from his experiments that the causes which lie at the bottom of the origin of sex in *Vaucheria*, as in other organisms, are shrouded in the deepest mystery. In the higher plants a number of experiments have been carried on for the purpose of learning the conditions which govern the production of staminate and pistillate flowers, or, in other words, the two kinds of sporophylls. From numerous empirical observations on

diœcious Spermatophyta, the inference has generally been drawn that nutrition bears an important relation to the development of the staminate and pistillate flowers; that scanty nutrition produces a preponderance of staminate plants, while an abundance of nutrition produces a preponderance of pistillate plants. For a period covering three decades several investigators have dealt with this question experimentally, notably K. Müller ('64), Haberlandt ('75, '77) and Hoffmann ('85). These experiments in general give some support to the inferences from observations, yet the results indicate that other influences are also at work, for the ratios of preponderance either way are not large enough to argue for this influence alone. In a majority of cases thick sowings, which in reality correspond to scanty nutrition, tend to produce staminate plants; while thin sowings tend to produce pistillate plants. In the case of the hemp (*Cannabis sativa*) Hoffmann found that these conditions had practically no influence. He suggests that the character of each may have been fixed during the development of the seed, or even that it may be due to late or early fecundation ('71).

In monœcious plants it has often been observed that pistillate flowers change to staminate ones and *vice versa*, and in diœcious plants pistillate ones sometimes are observed to change to staminate ones (the hemp, for example; see Nagel, 1879). K. Müller ('64) states that by scanty nutrition the pistillate flowers of *Zea mays* can be reduced to staminate ones.

Among the pines what are called androgynous cones have in some instances been observed. In *Pinus rigida* and *P. thunbergii*, for example, they occur (Masters ('68). Matsuda ('92) has described, in the case of *Pinus densiflora* of Japan, pistillate and androgynous flowers, which developed in place of the staminate flowers, and conversely staminate and androgynous flowers in place of pistillate ones. Fujii ('95) has observed that where the pistillate or androgynous flowers of *Pinus densiflora* occur in place of the staminate ones they are usually limited to the long shoots which are developed from the short ones of the previous year. The proximity of these transformed short shoots (Kurztriebe) to injuries of the long ones suggested that the cutting away of the long ones might induce the short ones to develop into long ones and the flowers which were in the position for staminate ones to become pistillate.

Fujii says: "In fact, the injuries producing such effect are frequently given by Japanese gardeners to the shoots of the year of *Pinus densiflora* in their operations of annual pollarding. But the 'Langtrieb' which is transformed from a 'Kurztrieb' of the last year does not necessarily bear female or hermaphrodite flowers in the positions of male flowers." To determine the influence of pollarding of the shoots he carried on experiments on this pine in the spring of 1895. He pollarded the shoots, so as, as he terms it, to induce the nourishment to be employed in the development of the flowers and short shoots near the seat of injury; in other cases one or two shoots were preserved, while all the adjacent shoots of last year's growth at the top of the branch were removed, and, farther, both of these processes were combined. Out of the 45 branches experimented on, and on which there were no signs of previous injury, there were nine pistillate or androgynous flowers in place of staminate ones; in 21 branches with signs of previous injury five were transformed, while in 2,283 not experimented on, and with no signs of previous injury, only seven were transformed. Such abnormal flowers, then, are due largely to the injuries upon the adjacent shoots, and, Fujii thinks, largely to the increased amount of nourishment which is conveyed to them as a result of this.

From the experiments thus far conducted upon the determination of sex in plants or upon the determination of staminate or pistillate members of the flowers, nutrition has at least some influence in building up the nourishing tissue for the two different organs or members. This can in part be explained on the ground that antheridia and staminate members of the plant are more or less short lived in comparison with the archegonia and pistillate members, the latter requiring more bulk of tissue to serve the purpose of protection and nourishment to the egg and embryo. It is thus evident that while some progress has been made in the study of this question we are far from a solution of it. Experiment has proceeded largely from a single standpoint, viz., that of the influence of nutrition. Other factors should be taken into consideration, for there are evidently other external influences and internal forces which play an important rôle, as well as certain correlation processes, perhaps connected with the osmotic activities of the cell sap.

The relation of the parts of the flower to the foliage leaves is a subject which has from time to time called forth discussion. That they are but modifications of the foliage leaf, constituents of the leaf concept, is the contention of the metamorphosis theory, and that the so-called sporophylls are modified foliage leaves, is accepted with little hesitation by nearly all botanists, though it would be very difficult, it seems to me, for any one to present any very strong argument from a phylogenetic standpoint in favor of the foliage leaf being the primary form in its evolution on the sporophyte, and that the sporophyll is a modern adaptation of the foliage leaf. Numerous cases are known of intermediate forms between sporophylls and foliage leaves both in the Spermatophyta and Pteridophyta. These are sometimes regarded as showing reversion, or indicating atavism, or in the case of some of the ferns as being contracted and partially fertile conditions of the foliage leaf. There has been a great deal of speculation regarding these interesting abnormal forms, but very little experimentation to determine the causes or conditions which govern the processes.

In 1894 I succeeded in producing a large series of these intermediate forms in the sensitive fern (*Onoclea sensibilis*). The experiments were carried on at the time for the especial purpose of determining whether in this species the partially developed sporophyll could be made to change to a foliage leaf and yet possess characters which would identify it as a transformed sporophyll. The experiments were carried on where there were a large number of the fern plants. When the first foliage leaves were about 25 cm. high they were cut away (about the middle of May). The second crop of foliage leaves were also cut away when they were about the same height during the month of June. During July, in which time the uninjured ferns were developing the normal sporophylls, those which were experimented upon presented a large series of gradations between the normal sporophyll and fully expanded foliage leaves. Among these examples there are all intermediate stages from sporophylls which show very slight expansions of the distal portion of the sporophyll and the distal portions of the pinnæ, until we reach forms which it is very difficult to distinguish from the normal foliage leaf. Accompanying these changes are all stages in the sterilization of the sporangia (and the formation of prothalloid growths), on some more broadly expanded sporophylls there being only faint evidences of the indusia.

The following year (1895) similar experiments were carried on with the ostrich fern (*Onoclea struthiopteris*) and similar results were obtained. At the time that these experiments were conducted I was unaware of

the experiments performed by Goebel on the ostrich fern. The results he reached were the same; the sporophyll was more or less completely transformed to a foliage leaf. Goebel regards this as the result of the correlation processes, and looks upon it as indicating that the sporophyll is a transformed foliage leaf, and that the experiment proves the reality here of the modification which was suggested in the theory of metamorphosis, and thus the foliage leaf is looked upon by him as the primary form. Another interpretation has been given to these results, viz., that they strengthen the view that the sporophyll, from a phylogenetic standpoint, is primary, while the foliage leaf is secondary. What one interprets as a reversion another regards as indicating a mode of progress in the sterilization of potentially sporogenous tissue and its conversion into assimilatory tissue. It is, perhaps, rather to be explained by the adaptive equipoise of the correlative processes existing between the vegetative and fruiting portions of the plant, which is inherited from earlier times. Rather when spore production appears on the sporophyte could this process be looked upon as a reversion to the primary office of the sporophyte, so that in spore production of the higher plants we may have a constantly recurring reversion to a process which in the remote past was the sole function of this phase of the plant. In this way might be explained those cases where sporangia occur on the normal foliage leaf of *Botrychium*, and some peculiar cases which I have observed in *Osmunda cinnamomea*. In some of the examples of this species it would appear that growth of the leaf was marked by three different periods even after the fundament was outlined, the first a vegetative, second a spore-producing, and third a vegetative again ; for the basal portions of the leaf are expanded, the middle portions spore-bearing, the passage into the middle portions being gradual, so that many sporangia are on the margins of quite well-developed pinnæ. These gradations of the basal part of the leaf, and their relation to the expanded vegetative basal portion, showing that the transition here has been from partially formed foliage leaf to sporophyll after the fundament was established, and later the increments of the vegetative part from the middle toward the terminal portion, as shown by the more and more expanded condition of the lamina and decreasing sporangia, indicate that vegetative forces are again in the ascendency. This suggests how unstable is the poise between the vegetative leaf and sporophyll in structure and function in the case of this species.

For two successive years I have endeavored by experiment to produce this transformation in *Osmunda cinnamomea*, but thus far without sufficiently marked results. The stem of the plant is stout, and this, together with the bases of the leaves closely overlapping, contains considerable amounts of stored nutriment, which make it difficult to produce the results by simply cutting off the foliage leaves. The fact that these transformations are known to occur where fire has overspread the ground, and, as I have observed, where the logging in the woods seriously injured the stools of the plant, it would seem that deeper seated injuries than the mere removal of foliage leaves would be required to produce the transformation in this species. It may be that such injury as results from fire or the severe crushing of the stools of the plant would be sufficient to disturb the equilibrium which existed at the time, that the action of the correlative forces is changed thereby, and there would be a tendency for the partially developed foliage leaves to form sporangia, then when growth has proceeded for a time this balance is again changed.

The theory that the foliage leaves of the

sporophyte have been derived by a process of sterilization, and that the transformation of sporophylls to foliage leaves in an individual indicates the mode of progress in this sterilization, does not necessarily involve the idea that the sporophyll of any of the ferns, as they now exist, was the primary form of the leaf in that species, and that by sterilization of some of the sporophylls, the present dimorphic form of the leaves was brought about. The process of the evolution of the leaf has probably been a gradual one and extends back to some ancestral form now totally unknown. One might differ from Professor Bower in the examples selected by him to illustrate the course of progress from a simple and slightly differentiated sporophyte to that exhibited in the various groups of the Pteridophyta, but it seems to me that he is right in so far as his contention for the evolution of vegetative and assimilatory members of the sporophyte can be illustrated by a comparison of the different degrees of complexity represented by it in different groups, and that this illustrates the mode of progress, as he terms it, in the sterilization of potential sporangenous tissue.

On this point it appears that Professor Bower has been unjustly criticised. The forms selected to illustrate his theory were chosen not to represent ancestral forms, or direct phylogenetic lines, but solely for the purpose of illustrating the gradual transference of spore-bearing tissue from a central to a peripheral position, and the gradual eruption and separation of spore-bearing areas, with the final sterilization of some of these outgrowths.

To maintain that in phylogeny the sporophyll is a transformed foliage leaf would necessitate the predication of ancestral plants with only foliage leaves, and that in the case of these plants the vegetative condition of the sporophyte was the primary one, spore production being a later developed function. Of the forms below the Pteridophyta, so far as our present evidence goes, the sporophyte originated through what Bower calls the gradual elaboration of the zygote. All through the Bryophyta, wherever a sporophyte is developed, spore production constantly recurs in each cycle of the development, and yet there is no indication of any foliar organs on the sporophyte. The simplest forms of the sporophyte contain no assimilatory tissue, but in the more complex forms assimilatory tissue is developed to some extent, showing that the correlative forces which formerly were so balanced as to confine the vegetative growth to the gametophyte, and fruiting to the sporophyte, are later changing; that vegetative growth and assimilation are being transferred to the sporophyte, while the latter still retains the function of spore production, though postponed in the ontogeny of the plant.

If we cannot accept some such theory for the origin of sporophylls and foliage leaves by gradual changes in potentially sporogenous tissue somewhat on the lines indicated by Bower, it seems to me it would be necessary, as already suggested, to predicate an ancestral form for the Pteridophyta in which spore production was absent. That is, spore production, in the sporophyte of ancestral forms of the Pteridophyta, may never have existed in the early period of its evolution and spore production may have been a later development. But this, judging from the evidence which we have, is improbable, since the gametophyte alone would then be concerned in transmitting hereditary characters, unless the sporophyte through a long period developed the gametophyte stage through apospory. Bower says in taking issue with Goebel's statement that the experiments on Onoclea prove the sporophyll to be a transformed foliage leaf: "I assert, on the other hand, that this is not proved, and that a good

case could be made out for priority of the sporophyte; in which event the conclusion would need to be inverted, *the foliage leaf would be looked upon as a sterilized sporophyll.* This would be perfectly consistent with the *correlation* demonstrated by Professor Goebel's experiments, as also with the intercalation of a vegetative phase between the zygote and the production of spores." In another place he says: "To me, whether we take such simple cases as the Lycopods or the more complex case of the Filicineæ, the sporangium is not a gift showered by a bountiful Providence upon pre-existent foliage leaves; the sporangium, like other parts, must be looked upon from the point of view of descent; its production in the individual or in the race may be deferred, owing to the intercalation of a vegetative phase, as above explained; while, in certain cases at least, we probably see in the foliage leaf the result of the sterilization of sporophylls. If this be so, much may be then said in favor of the view that the appearance of sporangia upon the later formed leaves of the individual is a reversion to a more ancient type rather than a metamorphosis of a progressive order."

As I have endeavored to point out in another place, if a disturbance of these correlative processes results in the transference of sporophyllary organs to vegetative ones on the sporophyte "why should there not be a similar influence brought to bear on the sporophyte, when the same function resides solely in the gametophyte, and a disturbing element of this kind is introduced? To me there are convincing grounds for believing that this influence was a very potent, though not the only one in the early evolution of sporophytic assimilatory organs. By this I do not mean that in the Bryophyta, for example, injury to the gametophyte would now produce distinct vegetative organs on the sporophyte, which would tend to make it independent of the gametophyte. But that in the bryophyte-like ancestors of the pteridophytes an influence of this kind did actually take place, appears to me reasonable.

"In the gradual passage from an aquatic life, for which the gametophyte was better suited, to a terrestrial existence, for which it was unadapted, a disturbance of the correlative processes was introduced. This would not only assist in the sterilization of some of the sporogenous tissue, which was taking place, but there would also be a tendency to force this function on some of the sterilized portions of the sporophyte, and to expand them into organs better adapted to this office. As eruptions in the mass of sporogenous tissue took place and sporophylls were evolved, this would be accompanied by the transference of the assimilatory function of the gametophyte to some of these sporophylls."

Because sporophytic vegetation is more suited to dry land conditions than the gametophytic vegetation, it has come to be the dominating feature of land areas. Because the sporophyte in the Pteridophyta and Spermatophyta leads an independent existence from the gametophyte, it must possess assimilatory tissue of its own, and this is necessarily developed first in the ontogeny, but it does not necessarily follow, therefore, that the foliage leaf was the primary organ in the phylogeny of the sporophyte. The provision for the development of a large number of spores in the thallophytes, so that many may perish and still some remain to perpetuate the race, is laid hold on by the bryophytes where the mass of spore-bearing cells increases and becomes more stable, for purposes of the greatest importance. Instead of perishing, some of the sporogenous tissue forms protecting envelopes, then supporting and conducting tissue, and finally, in the pteridophytes and spermatophytes, nutritive and assimilatory structures are developed. Nature is prodi-

gal in the production of initial elementary structures and organs. But while making abundant provision for the life of the organism through the favored few, she has learned to turn an increasing number of the unfavored ones to good account. Acted upon by external agents and by internal forces, and a changing environment, advance is made step by step to higher, more stable and prolonged periods.

While we have not yet solved any one of these problems, the results of experimental morphology are sufficient to indicate the great importance of the subject and the need of fuller data from a much larger number of plants. If thus far the results of experiments have not been in all cases sufficient to overthrow the previous notions entertained touching the subjects involved, they at least show that there are good grounds for new thoughts and new interpretations, or for the amendment of the existing theories. While there is not time for detailing, even briefly, another line of experiment, viz, that upon leaf arrangement, I might simply call attention to the importance of the experiments conducted by Schumann and Weisse from the standpoint of Schwendener's mechanical theory of leaf arrangement ('78). Weisse ('94) shows that the validity of the so-called theory of the spiral arrangement of the leaves on the axis may be questioned, and that there are good grounds for the opening of the discussion again. It seems to me, therefore, that the final judgment upon either side of all these questions cannot now be given. It is for the purpose of bringing fresh to the minds of the working botanists the importance of the experimental method in dealing with these problems of nature that this discussion is presented as a short contribution to the subject of experimental morphology of plants.

GEO. F. ATKINSON.

CORNELL UNIVERSITY.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

DURING the Toronto meeting of the British Association for the Advancement of Science the Section in Physiology held seven sessions under the presidency of Professor Michael Foster (Cambridge). The sessions were held in the Biological Building of the University of Toronto, and forty-one papers and demonstrations were presented. The proceedings began upon Thursday, August 19th, with the admirable address of the President, which will be printed in a future number of SCIENCE. The sectional papers of that day related in general to the subject of motion. Professor H. P. Bowditch (Harvard) discussed the rhythm of smooth muscles. Rings from the frog's stomach, when suspended, exhibit sooner or later spontaneous contractions, which continue for from forty-five minutes to twenty-four hours. The graphic curve of such contractions seems to be compound, being formed by the superposition of two waves, which represent two rhythmic contractions of different rates. Sets of contractions are also repeated rhythmically. Professor G. C. Huber (Michigan) gave the results of further researches on the innervation of motor tissues with especial reference to nerve-endings in the sensory muscle-spindles. The main points in this paper are given in SCIENCE, Vol. V., p. 908. Mr. O. F. F. Grünbaum (Cambridge) demonstrated by lantern slides the muscle-spindles in pathological conditions. Professor F. S. Lee (Columbia) discussed the ear and the lateral line in fishes. These two organs are equilibrative in function, and the former is probably the phylogenetic derivative of the latter. Audition in the customary sense of the word is wanting in fishes, and first appears with the change from an aquatic to a land existence. Professor W. P. Lombard (Michigan) spoke on the effect of the frequency of excitations on the contractility of muscles. Dr. J. H.

Kellogg reported the results of a dynamometric study of the strength of the several groups of muscles and the relation of the corresponding homologous groups of muscles in man.

The session of Friday morning, August 20th, was devoted mainly to the presentation of papers on the circulation. Professor G. N. Stewart (Western Reserve) gave a large number of measurements of the output of the mammalian heart examined by a new method. Professor W. T. Porter (Harvard) reported his observations on the mammalian heart concerning the cause of the heart-beat, fibrillary contractions, the influence of ventricular systole on the blood-flow through the heart-muscle, and the circulation through the veins of Thebesius. (See SCIENCE, p. 905, 906.) Professor Karl Hürthle (Breslau) discussed the resistance of the vascular channels. Resistance depends on two factors—the internal friction of the blood and the dimensions of the tubular system. Measurements of the former by the author's method give the result: internal friction of distilled water at 37°C.: that of blood : : 1 : 4.5 (dog), 4.1 (cat), 3.2 (rabbit). From this and certain other data, the author calculates the resistance expressed in terms of the dimensions of a tube through which, under the given conditions, the same quantity of blood could flow. The resistance through the several organs and over the entire vascular course is now being measured. Dr. W. H. Gaskell (Cambridge) gave a comparative résumé of the physiology of the cardiac branches of the vagus nerve in the five main divisions of the vertebrates. Professor A. R. Cushny (Michigan) discussed rythmical variations in the strength of the contractions of the mammalian heart. Professor W. H. Thompson (Belfast) presented a report upon the physiological effects of peptone and its precursors when introduced into the circulation. The research is in the hands of a committee consisting of Professors Schäfer, Sherrington, Boyce and Thompson, and the work of the past year has been carried on by Professor Thompson. The effects of Witte's peptone, pure peptone, anti-peptone and deutero-albumose were given in detail. Professor E. W. Reid (Dundee) presented the results of experiments on the absorption of serum in the intestine. Water and organic and inorganic solids are absorbed against an excess of hydrostatic pressure in the blood-vessels. The results seem to exclude explanation by osmosis, filtration into capillaries or lacteals, imbibition, electro-osmotic action, and aspiration by the blood-current.

In the afternoon of Friday Professor Anderson Stuart (Sidney) spoke upon a newly discovered function of the canal of Stilling in the vitreous humor in receiving lymph during the accommodation of the eye. Professor Stuart also described a number of simple pieces of physiological apparatus which he had found useful for demonstrative purposes. Dr. Noel Paton (Edinburgh) discussed the phosphorus metabolism of the salmon in fresh water, with especial reference to the diminution of phosphorus in the muscle and its increase in the reproductive organs. The loss of phosphorus from the muscle is barely sufficient to account for the gain in the ovary, and amply sufficient for the gain in the testis. But the phosphorus compounds—chiefly lecithin and ichthulin in the ovary and nuclein in the testis—must be formed synthetically. Lecithin is probably one of the first stages in the construction of nucleo-compounds. Professor J. Loeb (Chicago) demonstrated and discussed certain electrostatical stimulative effects upon nerves, which might be mistaken for electro-magnetic effects. Professor G. Lusk (Yale) gave the results of experiments on the gastric inversion of cane sugar by hydrochloric acid, which show that the acidity of the

gastric juice is sufficient to produce such inversion as takes place in the stomach.

The section held no session on Saturday, the majority of the members making the excursion to Niagara.

Monday forenoon was devoted to the subject of neurology. Professor Carl Huber (Michigan) gave an account of his study of the comparative histology of the cells of the sympathetic nervous system. (See SCIENCE, Vol. V., p. 132.) Dr. J. J. Mackenzie (Toronto) spoke on the microchemistry of nerve-cells. Mr. W. B. Warrington gave the details of an investigation of the changes in nerve-cells in various pathological conditions, the latter being caused by various organic poisons, anæmia, the division of peripheral nerves, and the division of the posterior roots. Professer A. Waller (London), who is a member of the committee previously appointed by the Association to investigate the changes which are associated with the functional activity of nerve-cells and their peripheral extensions, and who has been working upon the electro-physiology of isolated nerve, made an elaborate and valuable roport upon the action of acids, alkalies, carbonic acid, tetanization and temperature upon electrotonic currents in nerve. Such currents are physiological, as well as physical. Normally the anodic current (A) is greater than the kathodic (K), in the proportion of 4 or 5 to 1. Rise of temperature to 40° causes diminution of A and increase of K. K is favored by acidification and tetanization, disfavored by basification; alterations of A are less uniform and characteristic. Tetanization and CO_2 have similar effects upon the electrotonic currents. In Dr. Waller's opinion this proves that the tetanization of an isolated nerve gives rise to a production of CO_2. In view of the impossibility heretofore of obtaining any evidence whatever of metabolism in an acting nerve, this conclusion is most important and suggestive, as bearing upon the nature of the nerve impulse. During the presentation of Dr. Waller's paper Miss Welby demonstrated the method used in his laboratory of applying anæsthetics to isolated tissues, employing for the purpose cardiac muscle. Professor Charles Richet (Paris) announced his discovery of a refractory period in the cerebral and medullary nervous centers of the dog. If these be rhythmically stimulated they will respond to either every stimulus or only every other one, according to the temperature and rate of excitation. The duration of the period is 0.1″ at 30° C. Man has a refractory period, since he cannot think at a greater frequency than 10 to 12 per second. Hence the psychological unit of time, or the elementary period of consciousness, is about 0.1″, which, therefore, represents the duration of vibration of the nerve-center.

Monday afternoon was given up to demonstrations. Professor W. P. Lombard (Michigan) showed a cheap and simple chronograph. Professor C. S. Sherrington (Liverpool) demonstrated various new facts regarding visual contrast and flicker. Professor A. B. Macallum (Toronto) showed microscopic specimens illustrating the distribution of iron in cells, and Professors W. A. Herdman and R. Boyce (Liverpool) microscopic specimens illustrating the presence of copper in cells.

On Tuesday morning the Sections in Physiology and Botany held a combined meeting to discuss the chemistry and structure of the cell. This attracted a considerable audience and was one of the most interesting of the sessions. The discussion was opened by Professor R. Meldola (London), who spoke on the rationale of chemical synthesis. Comments were made by Professors J. R. Green (Cambridge), W. D. Halliburton (London), I. Remsen (Johns Hopkins), H. Marshall Ward (Cambridge), and H. E. Armstrong (London). Professor J. R. Green (Cambridge) presented experi-

mental evidence of the existence in yeast of an alcohol-producing enzyme. Professor A. B. Macallum (Toronto) presented certain new views on the significance of intracellular structures and organs. According to him the centrosphere is the oldest part of the cell. The nucleus and the cytoplasm are secondary structures. This explains the fact that in cell-division the division of the centrosome precedes that of the rest of the cell. These views were opposed by Mr. H. Wager (Leeds), who gave strong evidence for the presence of a nucleus in the yeast-cell, and by Professor J. B. Farmer (London).

The final session was held on Wednesday forenoon and was devoted to psychological and miscellaneous papers. Professor W. D. Halliburton (London), on behalf of himself and Dr. Mott, discussed the action of cholin, neurin and allied substances on the circulation, in connection with the discovery by them, in the cerebro-spinal fluid in certain forms of insanity, of a substance which appears identical with cholin and depresses blood-pressure by acting upon the heart. Professor R. Boyce (Liverpool), on behalf of himself and Professor W. A. Herdman (Liverpool), discussed the presence of copper in animal cells. Papers were read by Dr. T. W. G. McKay on intestinal absorption of hæmoglobin and ferratin, by Mr. R. R. Bensley (Toronto) on the morphology and physiology of gastric cells, and by Mr. O. F. F. Grünbaum (Cambridge) on visual reaction to intermittent stimulation. Professor Wesley Mills (McGill) discussed the functional development of the cerebral cortex in different groups of animals (see SCIENCE, Vol. V., p. 134), and the psychic development of young animals. In the latter paper he presented the results of a correlation of the psychic development of the dog, cat, rabbit, guinea-pig, rat, and bird with the development of the cortical centers. Professor C. Lloyd Morgan (Bristol) read a suggestive paper on the physiology of instinct. The essential part of the objective aspect of instinctive activity is the coordination of outgoing impulses. This activity is at first unconscious, but later, by the coming in of afferent impulses, consciousness may appear. Professor L. Witmer (Pennsylvania) discussed the nature and physical basis of pain. Pain is a sensation, the central organ of which consists of the sensori-motor centers; no special pain nerves exist.

On account of the full program comparatively little general discussion of the papers was possible, and this constituted the one drawback of the meeting. The sectional committee, the membership of which has already been printed in SCIENCE, p. 335, held daily sessions, and the usual grants for research were asked for.

FREDERIC S. LEE.

COLUMBIA UNIVERSITY.

THE PATAGONIAN EXPEDITION FROM PRINCETON UNIVERSITY.

THIS expedition, dispatched to Patagonia from Princeton University in February, 1896, returned during August. It was under the auspices of Professor W. B. Scott, of the Department of Geology, and had for its object the collecting of vertebrate fossils from the Tertiary deposits, and the skins and skeletons of recent birds and mammals. It was directly in charge of Mr. J. B. Hatcher and his assistant, Mr. O. A. Peterson.

The objective point was the Port of Gallegos, on the east coast of southern Patagonia, which was reached April 29, 1896. From this point investigations were conducted, first along the coast from Sandy Point, in the Straits of Magellan, to Port Desire, on the north. In this region many interesting fossil forms were secured and a nearly complete series of living birds, mammals and plants. After spending several

months in the coast region, an expedition was made into the interior, into the little known lake region about the head waters of the Santa Cruz river and to the northward into an absolutely unknown region of the Cordilleros. Here many new glaciers were discovered and important water courses located.

The time spent in this region was most enjoyable, and the results there attained contributed even more to the success of the trip than those nearer the coast. Being an unexplored country not only were new facts relating to the geography of the region discovered, but many animals and plants new to science were also collected; and the series of observations made, and facts obtained, relating to the age of the Cordilleros and other geological phenomena of the entire region, are of the greatest value. Scattering over the plains region of the interior were found numerous volcanic cones hitherto unreported which were shown to have been the source of the great lava beds which in many places are spread in great sheets over the surface of the country.

On account of the difficult travelling and the length of time consumed on this trip into the interior, it was absolutely impossible to take any great supply of provisions, so that it became necessary to limit the personnel of the expedition to Messrs. Hatcher and Peterson, who were gone five months on this trip, during which time not only was it impossible for them to receive or dispatch any mail, but they never met with or saw a single human being but their two selves.

The result of the work done in Patagonia may be briefly summarized as follows:

The discovery of many new facts relating to the geography of the region.

The discovery of several geological horizons new to Patagonia.

The making of a complete geological section from the igneous rocks forming the mass of the Cordilleros to the uppermost Tertiary rocks, and extending from the Cordilleros to the Atlantic coast.

The collecting of a nearly complete series of the mosses, hepatical and flowering plants, not including grasses; of some 800 skins and skeletons of recent birds and animals and about eight tons of fossils, including more than 1,000 skulls and many nearly complete skeletons—altogether, the most valuable collection from that region to be found anywhere in the world.

After spending a little more than a year on the mainland, the expedition proceeded to Tierra del Fuego and the adjoining islands, where important collections were also made, especially of the plants of that archipelago, and observations were made concerning the geology and paleontology of the islands, which it is believed will be of considerable importance. Some attention was also given to the Indians of this region, especially of the Channel and Canoe Indians, who live almost entirely in frail boats of their own manufacture and subsist wholly upon shell fish, which they are able to pick up in great abundance along the shore. The great accumulation of shell heaps observed at certain points along the shores is believed to point to a great antiquity for this exceedingly primitive tribe.

Throughout their work the Argentine government was very generous and courteous to the expedition, giving to its members transportation on its war vessels from Buenos Aires to Gallegos and return, and offering to place at its disposal a smaller vessel for use in researches among the islands.

SCIENTIFIC NOTES AND NEWS.

GRANTS FROM THE BRITISH ASSOCIATION FOR SCIENTIFIC RESEARCH.

As we have already noted, the British Association appropriated at the Toronto meeting £1,350 (more than $6,500) to committees for

scientific work. The sum was larger than usual, as the the large attendance at the Liverpool meeting left a surplus, and it was wished to favor this year the inauguration or continuation of special work in Canada. It is with reluctance that we state for comparison that last year the American Association appropriated $200 and this year $100 for scientific work. It should be remembered that such appropriations not only contribute greatly to the advancement of science, but also add much to the interest of the meetings at which the reports of the committees are presented.

The responsible member of the committee, the subject of the work and the amount in pounds each of the appropriations is as follows:

	£
Mathematics and Physics.—Professor Carey Foster: Electrical Standards	75 0 0
Mr. G. J. Symons: Seismological Observations	75 0 0
Dr. E. Atkinson: Abstracts of Physical Papers	100 0 0
Rev. R. Harley: Calculation of Certain Integrals	20 0 0
Mr. W. N. Shaw: Electrolysis and Electrochemistry	35 0 0
Professor H. L. Callendar: Meteorological Observatory at Montreal	50 0 0
Chemistry.—Sir H. E. Roscoe: Wave-length Tables of the Spectra of the Elements	20 0 0
Professor J. Emerson Reynolds: Electrolysis Quantitative Analysis	12 0 0
Dr. T. E. Thorpe: Action upon Light Dyed Colours	8 0 0
Sir J. Evans: Promotion of Agriculture	5 0 0
Geology.—Professor E. Hull: Erratic Blocks	5 0 0
Professor T. G. Bonney: Investigation of a Coral Reef	40 0 0
Sir W. H. Flower: Fauna of Singapore Caves (unexpended balance in hand, 40*l.*)	—
Professor J. Geikie: Photographs of Geological Interest	10 0 0
Mr. J. E. Marr: Life-zones in British Carboniferous Rocks (unexpended balance in hand)	—
Professor W. Boyd Dawkins: Remains of the Irish Elk in the Isle of Man (unexpended balance in hand)	—
Mr. T. F. Jamieson: Age of Rocks near Moreseat	10 0 0
Sir J. W. Dawson: Pleistocene Fauna and Flora in Canada	20 0 0
Zoology.—Professor W. A. Herdman: Table at the Zoological Station, Naples	100 0 0
Mr. G. C. Bourne: Table at the Biological Laboratory, Plymouth	20 0 0
Sir W. H. Flower: Index Generum et Specierum Animalium	100 0 0
Professor L. C. Miall: Biology of the Lakes of Ontario	75 0 0
Professor W. A. Herdman: Healthy and Unhealthy Oysters	30 0 0
Geography.—Mr. E. G. Ravenstein: Climatology of Tropical Africa	10 0 0
Economic Science and Statistics.—Professor H. Sidgwick: State Monopolies in other Countries	15 0 0
Mr. L. L. Price: Future Dealings in Raw Produce	10 0 0
Mechanical Science.—Mr. W. H. Preece: Small Screw Gauge	20 0 0
Anthropology.—Professor E. B. Tylor: Northwestern Tribes of Canada	75 0 0
Dr. R. Munro: Lake Village at Glastonbury	37 10 0
Mr. E. W. Brabrook: Ethnographical Survey (and unexpended balance in hand)	25 0 0
Mr. A. J. Evans: Silchester Excavation	7 10 0
Dr. G. M. Dawson: Ethnological Survey of Canada	75 0 0
Sir W. Turner: Anthropology and Natural History of Torres Strait	125 0 0
Physiology.—Dr. W. H. Gaskell: Investigation of Changes associated with the Functional Activity of Nerve Cells and their Peripheral Extensions	100 0 0
Botany.—Professor J. B. Farmer: Fertilization in Phæophyceæ	15 0 0
Corresponding Societies.—Professor R. Meldola: Preparation of Report	25 0 0

THE NEW YORK BOTANICAL GARDEN.

THE New York City Board of Estimate and Apportionment gave a public hearing on September 29th in the matter of the appropriation for the Bontanical Museum for the Botanical Garden in Bronx Park. Some persons have been objecting to the plans approved by the Park Board, but in the public hearing they only took exception in a general way to the use of a portion of a Park for a Botanical Garden. The Board of Estimate and Appropriation unanimously passed a resolution granting the appropriation, after listening to a statement from the trustees, which was as follows:

"The establishment of a Botanical Garden in the city of New York has been actively prosecuted since the year 1889, the necessary legislation having been obtained in an act passed in 1891 and amended in 1894 and 1896. The project through all this period received most cordial support from the city officials and from the public. The present Board of Managers was organized on March 21, 1895, and on June 18, 1895, the condition of the act of incorporation requiring the subscription of $250,000 was fully met. At a meeting of the managers, held on that date, a special committee of five members was appointed a committee on plans, and this committee has been since continued. The securing of the necessary $250,500 as a subscription fund was reported to the Commissioners of Parks, as authorized and directed by the act of incorporation, and the selection of site was duly accepted by the Board of Managers. On October 30, 1895, the present Board of Estimate and Apportionment authorized the issue of bonds to an amount not exceeding $25,000 for surveys, plans, etc.; but these have not been issued. Prior to the organization of the Board of Managers, many of the members of the corporation had given continuous study to the project since its inception. Several of them have made critical studies of botanical gardens in the Old World.

"The committee on plans, appointed in June, 1895, studied the subject in all its aspects for a year, with the aid of advice and suggestion from many botanists, landscape gardeners, architects, and others interested, in this country and in Europe, and determined the principal ends desirable to be reached, and the most economic, artistic and practical methods of reaching them, having always in mind the beautiful features of the grounds and the great value of these to the institution; their preservation has been determined on from the very first. On June 17, 1896, the preparation of a general plan to embody the results reached after this long and careful consideration was referred to a commission of experts, consisting of N. L. Britton, director-in-chief; R. W. Gibson, architect; John R. Brinley, civil and landscape engineer; Lucien M. Underwood, professor of botany, Columbia University; Samuel Henshaw, landscape gardener; Lincoln Pierson, secretary Lord & Burnham Company, greenhouse architects. All these are men well and favorably known in their professions, and it is maintained that in this commission were included all the elements necessary or desirable for the purpose of the general study, the determination of the detailed landscape treatment and special planting being wisely deferred until the general scheme had been approved; these will be taken up under the best advice obtainable."

GENERAL.

THE Eighth International Geological Congress will meet in Paris in 1900. In 1903 the place of meeting will be Vienna.

THE New York Academy of Sciences is in great need of a building for its meetings, for its library and as a center for the scientific life of the city. A university lecture room has not been a satisfactory place of meeting, and in view of the removal of Columbia University the Academy will this year meet at the Mott Memorial Library, 64 Madison Avenue. Visitors interested in the subjects presented are welcomed at the meetings, and citizens of New York should remember that the sections meet on Monday evenings as follows: Section of Astronomy and Physics, first Monday of the month; Section of Biology, second Monday; Section of Geology and Mineralogy, third Monday; Sections of Psychology, Anthropology and Philology, fourth Monday.

OF the other societies composing the Scientific Alliance of New York the Torrey Botanical Club will meet at the College of Pharmacy, the Linnæan Society and the Entomological Society at the American Museum of Natural History, the Chemical Society at the College of the City of New York, and the Mineralogical Club and the Microscopical Society at the Mott Memorial Library.

THE New York Section of the American Chemical Society will hold its annual meeting on October 15th. Officers for the ensuing year will be elected and the retiring President, Dr. Wm. McMurtrie, will make an address on 'Some Records of Recent Progress in Industrial Chemistry.' A special meeting of the Society was held on the evening of October 1st, in honor of Professor Henry E. Armstrong, of London, who came to this country to take part in the meeting of the British Association. An address was made by Dr. H. Carrington Bolton.

THE first section of the Brooklyn Museum of Arts and Sciences was dedicated on October 2d. Addresses were made by the President of the Board of Trustees, Mr. A. A. Healy, and by the Director of the Institute, Professor Franklin W. Hooper, by Mayor Wurster, of Brooklyn, and by President Eliot, of Harvard University,

who spoke on 'The Functions of Education in Democratic Society.' The present building, which is already crowded by the collections of art and natural history, was informally opened at the beginning of June, and was visited during August by 12,000 persons. The building as projected will be thirty-two times as large as the present structure, erected by the city of Brooklyn as one of its last public works at a cost of $300,000. The charter of the combined cities composing New York at the beginning of next year provides for the liberal maintenance of the Brooklyn Institute, which will be one of the chief centers of art, science and culture in the great city.

IN his address at the recent meeting of the Associated Chambers of Commerce, Sir Courtney Boyle announced his intention of establishing a museum of samples in connection with the British Board of Trade. The scope and objects of the museum would be similar to those of the recently established commercial museums at Philadelphia.

THE sum of £442 has been collected in British India as a contribution to the Pasteur Memorial Fund.

THE Maharaja of Patiala has presented the Indian government with a site for the Pasteur Institute to be established at Simla.

THE American Public Health Association will hold its twenty-fifth annual meeting at Philadelphia from the 26th to the 29th of October.

A SCHOOL of ethics and social philosophy has been formed in London, with a general committee including the Master of Balliol, Mr. Leslie Stephen, Mr. R. B. Haldane, Mr. W. L. Courtney, Professor Sully and Mrs. Bryant. The aim of the new school is to approach social questions from the side of psychology and ethics. Lectures have been promised by Professor Henry Sidgwick, Mr. Sidney Webb, Mr. F. W. H. Myers, Mr. Bosanquet, Professor Lewis Campbell and others.

THE first installment of a card catalogue of the New York Public Library was put in use at the Astor Library this week. Some twenty-five assistants are working under Dr. Billings on the catalogue, and it is hoped that it will be completed in about three years.

THE prize lists of the Institution of Civil Engineers for the session of 1896-97 awards the Howard prize of 50 guineas to Mr. Hilary Bauerman, in recognition of his work on the metallurgy of iron. For original papers presented to the Institution, Telford medals, with premiums of books or instruments, are awarded to Messrs. H. A. Humphrey, for 'The Mond Gas-Producer Plant and its Application;' to Colonel Pennycuick, R.E., for 'The Diversion of the Parivar;' to Mr. E. C. Shankland, for 'Steel Skeleton Construction in Chicago;' to Mr. Dugald Drummond, for 'High Pressure in Locomotives;' and to Mr. Thomas Holgate, for 'The Enrichment of Coal Gas.' George Stephenson medals and Telford premiums are awarded to Mr. Cruttwell, for 'The Tower-bridge Superstructure,' and to Professor Unwin, for 'A new Indentation Test for Determining the Hardness of Metals;' Watt medals and Telford premiums to Messrs. Hay and Fitzmaurice for their joint paper on 'The Blackwall Tunnel.'

THE Royal Society of New South Wales offers its medal and ten guineas for the best communication (provided it be of sufficient merit) containing the result of original research or observations on the following subjects; 'On the Iron-ore deposits of New South Wales' (time limit, May 1, 1898); 'On the Life History of the Australian Teredo and other specimens of Australasian wood-eating Marine Invertebrata, and on the means of protecting timber from their attacks' (time limit, May 1, 1899). The competition is not confined to members of the Society, nor to residents in Australia. The Society is fully sensible that the money value of the prize will not repay an investigator for the expenditure of his time and labor, but it is hoped that the honor will be regarded as a sufficient inducement and reward.

THE United States Civil Service Commission announces that on October 25, 1897, it will hold examinations to establish a register from which selections may be made to fill numerous minor vacancies in special and technical positions in the government service. A list of the examinations which will be held, and of the cities at which they may be taken, will be furnished on request.

SECRETARY WILSON, of the Agricultural Department, will, in his annual report, ask Congress to make an increase in the appropriation for the Bureau of Animal Industry, the Farmers' Bulletins and the Weather Bureau.

PROFESSOR WIESNER, of Vienna, has undertaken during the past summer, says *Nature*, a journey to Spitsbergen to complete his observations, previously made in the Tropics, as to the effect of light and other external conditions on the growth of plants.

THE members of the Stanford University party who have been engaged in branding seals by electricity on Pribyloff Islands have, as we learn from the daily press, arrived at Palo Alto. They claim that the experiment was successful. Besides the work of taking the seal census and building a fence enclosing the salt lagoon to prevent the redriving of bachelor seals, a number of bird skins, skeletons, insects and marine invertebrates were collected. The party consisted of Messrs. Greely, '98; Snodgrass, '99; Edwards, 1900; Bristow and Adams, 1900, and Instructor Farmer.

WE learn from the London *Times* that Miss Ormerod, of Torrington-house, St. Albans, continues to supply the leaflet on the common sparrow, and that several of the largest British landowners are interesting themselves in the endeavor to reduce the numbers of *Passer domesticus* to within reasonable limits. Since attention was first drawn to the matter a few weeks ago Miss Ormerod has received applications for the pamphlet from most unexpected places—Stavanger, St. Petersburg and Smyrna, for example. So great is the demand that yet another edition of 5,000 copies has been printed. Miss Ormerod sends the pamphlet free on a receipt of a stamp for postage and many copies should find their way to America.

A DESPATCH to the daily papers from Bombay states that the latest health statistics show that the bubonic plague is again active, having crept unobserved from hamlet to hamlet until a wide area is affected. The newspapers assert that the withdrawal of the medical officers for service with the troops on the frontier will entail consequences more disastrous than anything happening on the frontier.

AS we learn from *Nature*, the Commission du Musée d'Histoire Naturelle at Geneva has formed itself into a committee having for its object the erection of a monument to the memory of François Jules Pictet de la Rive. A site for the monument has been granted in front of the museum. Old students of the eminent investigator, and all who are interested in the work which he accomplished, are invited to send subscriptions for the memorial fund to MM. Lombard, Odier et Cie, Genève.

THE Icelandic Parliament has voted a subsidy for the laying of a cable from Scotland to Iceland by way of Faroe Islands. The Great Northern Telegraph Company will lay the cable during the early summer next year.

A REFUGEE hut on the Zugspite, the highest mountain in Germany (10,000 feet), near Garmisch, in the center of the Bavarian Highlands, has been opened. It stands on the Grat between the east and west peaks, affords accommodations for twenty-two guests, and has been erected at a cost of $10,000.

WITH the beginning of the next volume in January *The American Naturalist* will be published by Ginn & Co., Boston, New York and Chicago.

THE government of India and Lord George Hamilton have offered hearty congratulations to Sir Joseph Hooker on the occasion of the completion of the 'Flora of British India,' on which he has been engaged for twenty-five years. Sir Joseph will now undertake to complete the 'Flora of Ceylon,' left unfinished by the death of Dr. Trimen.

WE have received from John P. Morton & Son, Louisville, a guide to the Mammoth Cave, of Kentucky, by Horace C. Hovey and R. Ellsworth Call. Both of the authors have for years been familiar with the Mammoth Cave and have published works on American caverns. It is a great advantage to have a guide book by men of science, written with accuracy and without exaggeration. Visitors to the cave using this book will learn much of its geology and natural history, and it will also prove useful to those who are studying the scientific problems involved.

THE three leading articles of the October *Monist* deal with questions of evolution. The

first is a posthumous essay by the late George J. Romanes on 'Isolation as a Factor of Organic Evolution,' wherein Mr. Romanes discusses the contributions of Mr. Gulick to the theory of development, and gives it as his opinion that isolation is to be ranked with heredity and variability as 'the third pillar of a tripod on which is reared the whole superstructure of organic evolution.' He contends that even the principle of natural selection lies less deep, and makes of the latter a special case of isolation. Mr. Romanes also discusses his own doctrine of physiological selection. The second article, by Professor Eimer, of Tübingen, on 'The Origin of Species,' gives a concise digest of his views of evolution and exemplifies them by material and illustrations from his new forthcoming researches on butterflies. Eimer explains the origin of species, (1) by cessation of development at definite stages, (2) by evolution *per saltum*, and (3) by prevention of impregnation, which is similar to Romanes's physiological selection. He accords to natural selection a subordinate rôle only, having efficacy in the preservation but not in the origination of species. The transmutation of forms is controlled by orthogenesis, or definite development, and not by chance variation. The article is substantially Professor Eimer's Leyden address, which has not yet appeared in German. The third article is by Dr. Paul Topinard, and constitutes part of his series 'Man As a Member of Society,' in which the French anthropologist traces the influence of the factors which have affected social development from the beginning of civilization to its highest consummation.

THE following field meetings have been arranged by the Torrey Botanical Club, of New York:

Oct. 2d.—Mosholu, N. Y., N. Y. & P. R. R. Leave 155th St. (Ninth and Sixth Ave. Terminal, Manhattan Elevated R. R.) at 9:30 a. m. Returning, leave Mosholu at 12:37 p. m., or as desired. Object: Asters and Goldenrods. Excursion fare, 30 cts. Guide, Professor Burgess.

Oct. 9th.—Woodhaven, Long Island, L. I. R. R. Leave foot E. 34th St. at 1:30 p. m. Returning, leave Woodhaven as desired. Excursion fare, 35 cts. Guide, Mr. Hulst.

Oct. 16th.—Caryl, N. Y., N. Y. & P. R. R. Leave 155th St. at 1:00 p. m. Returning, leave Caryl at 5:17 or 5:47. Excursion fare, 30 cts. Guide, Mr. Constantine.

Oct. 23d.—Tarrytown and Sleepy Hollow, N. Y., N. Y. C. & H. R. R. R. Leave Grand Central Station at 1:00 p. m. Returning, leave Tarrytown at 5:37 p. m. Excursion fare, $1.00 Guide, Dr. Barnhart.

Oct. 30th.—Fort Lee, N. Y. Leave foot of 125th St. at 1:00 p. m. Returning as desired. Fare, 10 cts. Guide, Mr. Clute.

THE Committee of Fifty has requested Professor C. F. Hodge, Clark University, to gather the testimony of physiologists upon two topics relating to the practical teaching of the physiology of alcohol, and he is asking the following questions: *First*, as to the facts at our disposal, will you please give a list of the points which you consider sufficiently well established and of essential importance to the education of medical and university students? We wish to learn your own view of the physiology value of alcohol as a food, condiment, stimulant and medicine; its influence upon the tissues, organs and upon physiological processes. Please give also a list of the important points that you think are not sufficiently well proved to form a part of our teaching material, the points about which there is too much present difference of opinion. *Second*, to what extent do you think it wise to introduce alchohol physiology into elementary public school courses? I refer to the 'Scientific Temperance Instruction' promoted by the W. C. T. U., viz.: the requirement by law that the subject be given considererable prominence throughout the school course. Have you examined any of the 'approved and endorsed' physiologies? If so, which ones? What is your opinion of them? Finally, will you give a list of the arguments which seem most conclusive to yourself either for or against this method of preventing alcoholism?

MR. JOSEPH COLLINSON, writing to the London *Times*, from Walsingham, Durham county, after referring to the reports showing that three golden eagles have been killed in Great Britain within the last six months, and two last year, says: "Our country is being rapidly deprived of some of the noblest of its feathered inhabit-

ants. During the last few years a number of species have become extinct, and other species are fast disappearing. Most of us, unfortunately, have never had the pleasure of seeing many of these birds, and I agree with Hudson as to the cause—the direct action of man, the greedy collector mainly, whose methods are as discreditable as his action is injurious. No one wishes to preserve birds which are really harmful, if such there be; but all birds which are merely curious and rare should be strictly preserved by the legislature. There must be a remedy for this state of things. In pointing out that the Wild Birds Protection Acts should be made general in terms, I beg to suggest that, if all birds cannot be protected, the right principle is to enumerate just those species which are to be outside the pale of protection, not those which are to be within it."

IN Argentina, Cyprus and many other countries the locust is a formidable crop pest. A successful series of experiments carried out in Natal, a report of which has been published in that colony as a government notice, and is abstracted in the London *Times*, will prove of interest in many parts of the world. All attempts to suppress the locust scourge in Natal have proved only partially successful, with the exception of the plan of poisoning with arsenic, which, it is asserted, has met with absolute and unqualified success. The mixture used is prepared by heating four gallons of water to boiling point and then adding 1 pound of caustic soda. As soon as this is dissolved, 1 pound of arsenic is added, after which the liquid is well stirred and boiled for a few minutes, care being taken that the fumes are not inhaled. Being poisonous the mixture is kept under lock and key, but when required for use half a gallon of it is added to four gallons of hot or cold water, with brown sugar or treacle. Maize stalks, grass, etc., dipped in the mixture are placed along the roads and in the fields, and the material can also be splashed with a whitewash brush upon anything which the locusts are known to have a liking for. Attracted by the odor of the sugar or treacle over a distance of as much as 100 yards, the locusts will eat of the mixture and die. Arsenic is quite effective in destroying flying locusts, but as they come and go very suddenly, it is difficult to have the poison in readiness at the critical moment, and hence the most deadly blow can be dealt at the pest when it is in the hopper stage.

A MESSAGE to all interested in promoting the education of the deaf in Europe has been sent from the officers and directors of the Columbia Institution for the Deaf and Dumb, at Washington, signed by William McKinley, Edward M. Gallaudet and others. In the opening paragraphs it is stated that the oldest school for the deaf in the United States was established in 1817, eighty years ago. In 1857 there were nineteen schools, the buildings and grounds of which had cost $1,371,736, the annual support of which involved an expenditure of $285,416, and in which 1,771 pupils were being educated. At the present time there are eighty-nine schools, with 11,054 pupils under instruction during 1896. Thirty-four of these schools are in private hands, or are day-schools connected with the common-school system of some city or town. No statistics are available as to the cost of buildings and current expenses of these. For the fifty-five public institutions more than $11,000,000 have been expended on buildings and grounds, and nearly $2,000,000 are appropriated, annually, for current expenses. In every State of the Union public provision is made for the education of the deaf, thirty-nine States having schools of their own, and the six States without them providing for the education of their deaf children in the schools of the neighboring States.

IT is safe to predict that the forests of Alaska will be of greater value to the world than its gold. *Garden and Forest* devotes the leading article of the last issue to the subject, saying: "Trees cannot be cut lawfully in Alaska for timber or fuel, for there is no law which permits the sale of stumpage or timber-lands, and no law relating in any way to the forests but the one which forbids all shipment of wood from the Territory. There are a few sawmills in Alaska, however, and the number will soon be increased, and a large quantity of firewood is consumed at the salmon canneries and quartz mines, but the government gets nothing for it, and is powerless to prevent damage to the

public domain. Fortunately, the climate of southeastern Alaska is so humid that forest fires are rare and never very destructive, and reproduction is sure and rapid. These forests, therefore, even with American methods, will not soon or easily be destroyed; and here and to the southward, along the coast ranges and islands of British Columbia, through nine degrees of latitude from Cross Sound, at the north of Chicago Island, to the Straits of Fuca, is now the greatest continuous body of coniverous timber in the world, almost unmarked as yet by the axe, safe from fire and of easy access, from which the world will be able to draw great stores of material when the Redwoods and Douglas Spruces of the South have fallen, and the south-Atlantic and Gulf-shore pineries are only dim memories."

UNIVERSITY AND EDUCATIONAL NEWS.

THE attendance at the American colleges and universities will be larger this year than ever before. The numbers given at present are subject to revision, but nearly all institutions report the largest entrance classes ever recorded. At Harvard the Freshman class will be over 500. At Yale the academic Freshmen number about 350 (a slight decrease as compared with last year), and the Freshmen in the scientific department about 175. At Pennsylvania nearly 200 Freshmen were registered, about 35 more than last year. The entrance class at Princeton will number over 300.

THE colleges for women—Bryn Mawr, Vassar, Wellesley, Smith and others—also report an increased attendance. It is noteworthy that there are in the United States 139 colleges and universities exclusively for men and 162 exclusively for women.

IT is now stated that the estate of the late Henry M. Pierce will yield $750,000 to each of the five legatees, which include Harvard University and Massachusetts Institute of Technology.

BY the will of the late Dr. Antoine Ruppaner the Harvard Medical School will receive $10,000, to be called the Dr. Ruppaner Fund.

MR. H. H. HUNNEWELL has given $5,000 towards the endowment of the Surgical Laboratory of the Harvard Medical School.

THE Rev. Dr. Eliphalet Nott Potter, formerly President of Union College and of Hobart College, has accepted the presidency of the Cosmopolitan 'University' (Correspondence School).

DR. HANS REUSCH, director of the geological survey of Norway, has been appointed for 1897–98 to the Sturgis-Hooper professorship of geology in Harvard University, left vacant since the death of Professor J. D. Whitney a year ago. Dr. Reusch will lecture on Vulcanism during the first half year, treating volcanoes and eruptive rocks in general; earthquakes and movements of the earth's crust. In the second half year he will lecture on the Geology of Northern Europe, and its relations to general geology. The third hour of each week will be set apart for seminary work. In the spring Professor Reusch proposes to take part in the instruction of advanced students in the field.

IN addition to a number of assistants, the following instructors have been appointed at the Massachusetts Institute of Technology: Carl H. Clark, S.B., in mechanical engineering; Frederick A. Hannah, S.B., in mechanical engineering; Charles M. Spofford, S.B., in civil engineering. The following promotions have also been made: Arthur A. Noyes, S.B., Ph.D., associate professor of organic chemistry; Frank A. Laws, S.B., assistant professor of electrical measurements; Harry M. Goodwin, S.B., Ph.D., assistant professor of physics.

DISCUSSION AND CORRESPONDENCE.

RESULTS FROM THE HIGHEST KITE FLIGHT.

TO THE EDITOR OF SCIENCE: Aided by a grant from the Hodgkins Fund of the Smithsonian Institution, the Blue Hill Observatory is endeavoring to obtain meteorological records in the free air at heights exceeding 10,000 feet, and on September 19th such records were obtained at the highest level which kites are known by the writer to have attained.

The flight in question was conducted without mishaps by my assistants, Messrs. Clayton, Fergusson and Sweetland. On the day mentioned, the sky was clear and the wind blew from the south in gusts of from 20 to 35 miles an hour. The Richard baro-thermo-hygrograph, which weighs three pounds and was suspended 130 feet below two large kites of Mr.

Hargrave's form but of Mr. Clayton's construction, left the top of Blue Hill at noon. Similar smaller kites were attached to the main wire at intervals, so that the 20,670 feet of wire unreeled, which weighed 59 pounds, were sustained in the air by seven kites, having a total lifting surface of 213 square feet. Angular measurements at the windlass of the meteorograph enabled its height to be determined at definite times. The greatest height was reached at 4:17 p. m., when the meteorograph was 9,255 feet above Blue Hill, or 9,885 feet above the neighboring ocean. The meteorograph remained more than a mile above the sea during five hours. The reeling-in by means of the steam windlass occupied about two hours, and at 6:40 p. m. the meteorograph returned to the ground.

The automatic records were found to be smooth and distinct, with the exception of a portion of the barometer and hygrometer traces which was lost, owing, perhaps, to the temporary drying of the ink in the pens. The altitudes given by the barograph agreed closely with those computed from the angular measurements, showing that the barometric heights were nearly correct for the mean temperature encountered. The thermograph showed the lowest temperature to have been 38° at 9,255 feet above the hill, whereas on the hill at the same time the temperature was 63°, giving a mean decrease of only 1° for each 370 feet of ascent. The relative humidity varied greatly with altitude, although on the Hill it remained near 50 per cent. of saturation during the first half of the flight, increasing to about 80 per cent. at the end. Up to approximately 3,000 feet above sea-level the relative humidity increased, proving the existence of an invisible vapor stratum near the level of the cumulus cloud level. Higher it suddenly decreased, but increased to over 80 per cent. at the height of a mile, indicating the level of the alto-cumulus clouds. Above 8,000 feet the humidity was very low and probably less than 30 per cent. of saturation. The wind veered to west as the kites rose and became steadier, although its velocity was probably greater than near the hill top, since the pull on the windlass, which was counteracted in part by the weight of the suspended wire, exceeded 150 pounds when all the kites were high in the air.

A. LAWRENCE ROTCH.

BLUE HILL METEOROLOGICAL OBSERVATORY,
September 27, 1897.

'THE PRESENT EVOLUTION OF MAN.'

THE discussion of my review of his work, which is given by Mr. Archdall Reid on pp. 368–372 of your issue of September 3d, deserves some sort of reply. Yet I write with some reluctance, because I can only make such comments as must already have suggested themselves to many readers, without attempting an adequate treatment of the matters in dispute, which would require a book.

As regards Mr. Reid's theory of retrogression, I certainly have to say that I think it is wrong. The general statement 'that the ontogeny recapitulates the phylogeny' was a brilliant generalization when first made, and within reasonable limits accorded with the facts. But surely it has since been made a fetish of, and the version of it accepted in some quarters reminds one of the not uncommon popular notion that all animals are descended from one another in a direct line! According to Mr. Reid's view, I do not quite see how a female can transmit male characters, or *vice versa*, as undoubtedly occurs. If, for example, the beard is a comparatively new character, a woman, having no beard, is so far atavistic. Yet that beardless woman will have bearded male offspring, independently of the hairiness of the the father. But if such illustrations are objected to as being different from those intended by Mr. Reid, we may take the case of a seasonally dimorphic butterfly, which alternately loses and gains a set of characters. Here we have a series ABABAB, etc. If A is the oldest phase, then B reverts to A, and the opposite process should not be possible. When we contemplate the primary and secondary sexual characters and all the phenomena of dimorphism and polymorphism, I do not see how we can avoid the conclusion that germinal selection is a reality. At all events, the writer, after carefully reconsidering the matter in the light of Mr. Reid's new statement, is more than ever convinced of the validity of his former argument.

Now, as to 'social efficiency,' I am equally unconvinced of error. Is it not clear that social conditions powerfully affect the selection of individuals, and therefore a society or nation depends for its existence largely on its corporate virtue? It is a commonplace of history that the success of nations has depended largely on their laws and customs, those advancing and spreading whose social conditions favored the existence of brave and noble men. To the evolutionist, the most discouraging feature of our present day civilization is the survival of knaves and fools, while good men and true so often go to the wall. If this process is not checked, the inevitable result is the breaking-up of society and a return to some form of savagery.

Mr. Reid's argument about alcohol appears to depend largely on his theory of retrogression —a theory which I do not accept. Of course, I do not deny that the general use of alcohol will lead to a process of evolution against it, but I do deny the desirability of any race undergoing such a process. The practices of the Spartans led to the survival of the strongest among their children, while weaklings perished; and while we should not now imitate them, they were justified in so far as the survivors were best fitted to defend the community in a time when physical defense was of prime importance and incapables were a serious hindrance. But the survivors of the pot-house are not particularly valuable individuals in other respects, nor is the ability to remain unaffected in the presence of whiskey a guarantee of good citizenship. Those very nations which are said by Mr. Reid to drink heavily are the leading nations of the world to-day. If Greece was anciently drunken and now is temperate, by all means give us drunken Greece!

There are three kinds of people, thus:

1. Those who have strong desires and keep them within bounds or divert them into suitable channels for social reasons.

2. Those who have strong desires but do not keep them within bounds or divert them into suitable channels.

3. Those who have not strong desires.

Mr. Reid's alcoholic evolution would apparently give us the third class. Savages largely belong to the second. I maintain that both the second and third classes are wholly undesirable, and that the first is the one to make a successful nation and to prove itself the fittest in the struggle for existence.* The second may become the first more easily than the third, and hence is more desirable. As missionaries will say, give us a man who strongly believes something, however demoniacal, and we can do something with him; but give us a man with no beliefs and we are almost helpless.

I fear Mr. Reid will feel strongly the inadequacy of my reply to his criticism, but he will forgive me in view of the difficulty of expressing oneself on such subjects in a few words. One's opinions are founded on the sum-total of one's knowledge and experience, and cannot always find justification in a few paragraphs.

T. D. A. COCKERELL.

MESILLA, NEW MEXICO,
September 9, 1897.

SCIENTIFIC LITERATURE.

Elementary Solid Geometry and Mensuration. HENRY DALLAS THOMPSON, D.Sc., Ph.D., Professor of Mathematics in Princeton University. New York, The Macmillan Company. 1897. 8vo. Pp. vii+199.

* The best nation would be one which contrived the fullest expressions of its desires with the minimum of harm. Some repression would be necessary because some of our desires or feelings were developed under different conditions. Thus the desire to kill an enemy may formerly have been advantageous, but could not be allowed full play under existing social conditions. I think we all at times would be more pugnacious if we permitted ourselves absolute freedom! At the same time, there is no doubt that under present circumstances excessive repression works a great injury, as I stated in my former article. One may compare the desires of the people to water flowing through a valley; if it is permitted to flow where it will it may be useless for agriculture and may even do much damage; if it is merely dammed up it is equally useless and is likely to break loose and do more harm than in the first instance; but if, by skillful engineering, it is directed into suitable channels it may all be made available for mills and irrigation, while dangers of flooding are avoided. Let those who are engineering the United States remember this and aim neither to waste nor repress the desires and energies of the people, but use them all for the good of all.

Professor Thompson's text-book on Elementary Solid Geometry will be received with pleasure by American teachers of elementary mathematics. It fills an almost unoccupied place by confining itself to a narrow field. Colleges that do not require solid geometry for entrance will find it especially useful.

There are six chapters devoted to those parts of the elementary solid geometry ordinarily taught in our colleges and secondary schools, one appropriate chapter on the conic sections and one on mensuration. Each chapter, excepting the fifth, includes a large and well selected set of exercises.

Of course plane geometry is assumed but the first seven pages are given up to a careful, though designedly not exhaustive, consideration of certain fundamental notions. It is well stated that postulates are propositions 'taken without proof and upon which a train of reasoning is to be built,' and 'that it is no part of geometry to justify their use except in so far as their form is concerned.'

The sequence of propositions is developed in a scholarly and logical though decidedly conservative manner. The assumed construction is rigorously excluded. Many of the demonstrations are informal or left entirely to the student. The treatment of mensuration, apart from the geometry proper, is a good feature.

Considering the completeness of the work as a whole, the proof on pages 122 and 123 is noticeable. The theorem is: "The arc of a great circle less than a semicircle is the shortest line on the surface of a sphere between two given points not diametrically opposite." This proposition can only be proved by the use of some such postulate as the following: "The magnitude of a curved line is the limit toward which a broken line made up of consecutive chords of that curved line approaches when the number of chords is increased in such a manner that the chords are all diminished without limit." (Thomas S. Fiske, SCIENCE, Vol. IV., p. 724.) The words 'curved line' and 'broken line' are to be understood to mean respectively 'a line no part of which is a great circle arc' and 'a line made up of great circle arcs.' It seems unfortunate that such a postulate was not explicitly stated.

The terminology used is, on the whole, that of the average text-book, but the author has rendered a genuine service to the American geometric vocabulary by the introduction of Mr. Hayward's term 'cuboid' in place of the clumsy expression 'rectangular parallelepipid.'

The pages have a different appearance from those of the majority of our text-books, for they are solidly printed in the English style and no abbreviations are used.

C. B. WILLIAMS.

Thirty Years of Teaching. L. C. MIALL. London and New York, The Macmillan Company. 1897. Pp. viii+250. $1.00.

There is at present in the educational systems of all countries a circle—to call it a vicious circle would be over-emphatic—discriminating in favor of the classical languages and against the sciences. Those having a classical education at college and university find positions in the schools and in turn prepare boys for the classical course at college. The circle tends to remain unbroken. Teachers of the classics, being a great majority of all teachers, are apt to write most of the educational books. But from the point of view of the man of science a new era has begun when students of biology, such as Huxley, Morgan and Miall, begin to write on educational topics. The circle is broken and adjustment will follow in accordance with the physical principle of gravitation or the biological principle of the survival of the fittest.

Professor Miall's papers, reprinted with some additions from the *Journal of Education* (London), cover a wide range of subjects. He does not hesitate to write on the teaching of history, of geometry and of Latin grammar, as well as on nature study and school musuems, but throughout he urges by precept and by example the methods of natural science, of nature. Treat the child as a child, speak plainly, be interesting—such maxims are sufficiently trite, but they carry weight and influence when put in a book that treats the teacher as a teacher, and addresses him in a plain and interesting manner. Professor Miall's book will repay reading by the teacher, whether of the classics or of science, whether in the kindergarten or in the university.

PROFESSOR FLINDERS PETRIE'S SCHEME OF AN ETHNOLOGICAL STORE-HOUSE.

OF late years many scientific men have realized that the function of museums has been imperfectly understood. Some museum officials still regard museums more in the light of cabinets of curiosities than as serious teaching institutions. There are two distinct ways of treating museums from the educational point of view; these may briefly be described as the method of the text-book or the plan of dictionary; a combination of the two is always difficult and often impossible.

To explain my meaning: The bulk of people go to a museum for intellectual amusement; they are interested in natural objects or in the works of man, and they visit the museum in a laudable spirit of curiosity and with a desire to receive instruction. What these people require is a comparatively small number of objects suggestively arranged, with descriptive labels and accompanied by carefully chosen drawings, photographs and maps. In a properly arranged museum of this type it should be impossible for any intelligent visitor to leave it without having gained definite instruction. This is what I venture to call the text-book museum.

The more serious student, he who is seeking to advance knowledge, requires a very different type of museum. It is necessary that he should have access to a large number

of specimens, and it is here that the recent way of studying natural history and anthropology makes itself felt. Formerly students were satisfied if they could see one or two specimens of any given species of plant or animal, or an example of a shield or a spear of a given tribe. Now they have learnt that it is necessary to have long series of representatives of a species or of the various implements and weapons of primitive races. The old order belonged to the period when the fixity of species was an article of faith. To-day the naturalist is more interested in varieties and intermediate forms. Formerly the naturalist delighted in clearly cut classifications; now he revels in tracing the infinite gradations of nature and in endeavoring to learn their significance. The same applies to the anthropologist; those, for example, who study the decorative art of savage peoples or of pre-historic times have to visit as many museums as possible in order to get a sufficiently long series to enable them to trace the origin and distribution of certain designs. No museum is likely to be too large for such students. This is what may be termed the dictionary type of museum, and the specimens contained within it require, like the words in a dictionary, to be so arranged that they can be referred to with the minimum amount of trouble.

Those who have seen the great stores of duplicates in such museums as the National Museum, of Washington, or the Agassiz Museum, at Harvard, will recognize that our American colleagues have realized this need; but there are many practical difficulties. In large towns space is too valuable to admit of the accumulation of long series, unless they are to be so stored as to be studied under great difficulties; and certain large objects, such as many anthropological specimens, would occupy so much space as to preclude their being collected. Further, the cost of the dust-proof cases which are absolutely necessary in cities is very great.

Appreciating the need for the collecting of long series of anthropological specimens; for the desirability of having representatives, or representations, of all the objects made by vanishing tribes of natives; and for the advisability of keeping together associated objects from extensive archæological excavations, Professor Flinders Petrie has devised a scheme which will give the greatest possible storage space for a given expenditure. This scheme, which he brought before the meeting of the British Association at Liverpool, is briefly as follows:

The conditions for a repository with such a scope are so wholly different from those of existing museums that the proportions of expenditure are entirely changed. The essential and primary condition is that space shall be of minimum value; and, as it is desirable to keep down wages and the cost of moving objects, it is needful that, whatever the amount of expansion, no rearrangement should be necessary.

The type of structure must, therefore, be a long gallery, with lateral expansions to be built as any section increases. The galleries must be sufficiently wide apart to allow of any likely increase, however irregularly distributed.

An economical type of gallery would be one about 54 feet wide, divided into a nave and two aisles, the latter being subdivided into bays, 16 feet long. From these bays lateral expansions would be added whenever necessary. The walls should be low —say 10 feet—and about one-fourth of the roof should be of glass, which would ensure the galleries being well lighted.

The essence of the scheme is that the site shall be ordinary agricultural or wooded land, so that, however irregular the expansion, the unoccupied land will continue to be productive. Thus every possible need of the future can be accommodated without

incurring more immediate expense than is now requisite, and without any loss of interest on capital not utilized. For this purpose it would not be unreasonable to secure about 500 acres. On this land galleries of 54 feet wide, built in blocks of 100 bays, or 1600 feet in length, should be placed at about a furlong apart. This would allow of each gallery expanding on either side for about 250 feet of out-building.

Each gallery should have in the middle of its length a policeman's cottage (fireproof) with its windows looking along the inside of the gallery.

The site should be within a short journey from London; fairly dry and sandy if possible, and belts of trees should occupy the spaces between the galleries and thus reduce the effect of wind and rain.

No glass cases would be required except for a few objects that needed to be kept dry. There would be little dust in a wooded country, and the absence of any internal heating and the filtration of all air passing in would diminish the chance of dust. Where glass was desirable, large loose sheets could be laid over boxes or shelves, and specimens could be put out of reach by having strips of wood screwed down to secure the glass.

In his memorandum on this 'Proposed Repository for preserving Anthropological or other Objects,' which was printed in the Report of the Association for 1896 (p. 935), Professor Petrie enters into further details and offers suggestions concerning the constitution of the trustees and the duties of the keeper, as well as the disposition and ownership of the specimens. He estimates that the total cost *per annum* would be $2,450 for a building equal to half the British Museum exhibiting area, and the securing of space for future building up to 50 or 100 times the present exhibiting area. This amounts to $1\frac{1}{2}$ per cent. on the present annual grant to the British Museum at Bloomsbury.

This scheme led to a lively discussion and various objections were raised against more or fewer of the details, the most serious being that Professor Petrie had greatly underestimated the prime cost and the annual expenditure. In his reply he faced all the objections and admitted that even if the cost was greater than he had allowed for, some such scheme as his would be vastly cheaper than any museum as at present constituted.

It is first necessary to take a broad view of the situation, and to decide whether it is desirable to greatly increase our anthropological and archæological collections. Anthropology is so recent a science that its full importance is realized only by a few, and there is a very real danger that by the time the general public is educated to recognize its value a very considerable amount of material will have disappeared. All scientific anthropologists agree in asserting that it is desirable to collect examples of all objects made by vanishing peoples, and to preserve them for future generations. The next question is, whether sufficiently extensive collections can be stored in existing museums, and whether the cost of warehousing them and of providing suitable cases is not likely to be somewhat excessive—so much so as to cause the curators to limit the acquisition of specimens. It is much to be feared that this is what would actually occur; but what is required is that the accommodation should be of such a nature that no desirable specimen should ever be refused.

If existing museums are unsuited for indefinite expansion new ones must be built. Professor Petrie has proposed a scheme which may well form the basis of a discussion until it is replaced by a better. The great point to remember is that the problem is fast reaching an acute phase and it must soon be faced.

A. C. Haddon.

Cambridge, England.

THE FUR-SEAL INVESTIGATION OF 1897.

THE result of this season's work has mainly been to emphasize those of previous years, and particularly of 1896, and to show the futility of the suggestion that it is possible to preserve the numbers of the seals so long as pelagic sealing is continued. Careful examination of the breeding grounds and a count of the young made in several places shows that there has been a decrease of not far from fifteen per cent. among the females and thirty per cent. among the killable males. This loss is practically in accordance with the conclusions reached by the American commissioners in 1896, when the total number of seals was computed at between 450,000 and 500,000. It is known that after the census of seals was made 35,000, not less than eighty per cent. of them females, were killed at sea and that certainly 16,000 pups starved in consequence of pelagic sealing in Bering Sea. If to this is added the loss from natural causes, which is believed to be high, it is easy to see that a decrease of fifteen per cent. would be well within the mark.

To one familiar with the seals the loss shows itself in many ways; the seals playing in front of the breeding grounds, once so numerous and still to a considerable extent present in 1896, have nearly disappeared; places filled by breeding seals last year were this season occupied by old males alone, who waited in vain for any females, and localities which were inaccessible to the investigator last summer could easily be reached this summer. The average number of females present in a harem was also found to be smaller this year than last, and wherever it was practicable to count the live pups there was in every case a falling-off from the figures of 1896. The greater proportional falling-off of the bachelors, or killable males, was expected, and is the result of the pelagic killing of 1892–94, during which time over 100,000 seals were taken on the nortwest coast and 31,000 in Bering Sea.

The evil results of the small quota of seals killed on the Pribilof Islands between 1892–95 are seen in the superabundance of full or nearly full-grown males, hundreds of these being turned away from almost every drive. So numerous have the males become that should it ever prove possible to bring about a cessation of pelagic sealing it will be necessary to kill several thousands of the old bulls, whose relatively great numbers led to continuous fighting throughout the past summer, with a consequent disturbance of the breeding grounds and loss of many females.

Up to August 20th none of the yearlings branded as pups last year had made their appearance, nor was it expected that many of them, possibly not any, would be seen this year. This is partly for the reason that the yearlings arrive late and also because all the seals branded were females and few of these come on shore until they make their appearance on the breeding grounds as two-year olds. As probably not more than thirty per cent. of seals born reach the age of two years, it will be seen that comparatively few of the 377 pups branded may be expected next year. Six of the eleven adult females branded as an experiment were, however, seen, a large number when it is remembered that not over half of the females are on shore at any one time, that the total number of females is over 100,000 and that they are scattered over eight miles of shore. In every case the brands were plainly visible, although the seals had shed their coats after the branding was performed, and there is every reason to believe that branding is a success. It is scarcely necessary to say that reports of branded seals being taken on the coast of Japan have no foundation, as are the mythical herds which have been driven from the Pribilofs to parts unknown.

While the practical results of the season's work have been to more firmly strengthen the contentions of the United States, the scientific results have been more than expected. The observations of Mr. Clark, while throwing much light on the problem of early starvation of young, have also done much to explain the manner in which harems are formed and the massing of seals in particular spots when there is plenty of room and often better ground close at hand.

The noticeable scarcity of three-year old females indicates the truth of the supposition that the death rate is high, this being the only class whose abundance or scarcity could well be noted, owing to the great similarity in the appearance of the older seals. On only one point did the results of this year's observations differ materially from those of last year, and this is in respect to the cause of death among young seals. The conclusion reached last year that the great majority of deaths among the pups was due to their being trampled on by the old seals is found to be erroneous and that the mortality is caused by a parasite, a species of *Uncinaria*, found in the small intestine. This course of danger was pointed out by Dr. Stiles as a result of the examination of a very few specimens obtained in 1896, and the matter will be discussed at length later. It may be said that young seals—and they alone seem to be affected—dying from an attack of *Uncinaria* perish so quickly that they lose little of their fat and that the disease is practically over before the end of August.

Finally, the past summer was unusually dry and clear, these conditions greatly facilitating the work of the party from the U. S. Coast Survey which is engaged in making a careful survey of the islands and especially of the breeding grounds.

A BOTANICAL EXCURSION TO MEXICO.

Mexico is a profitable place for the botanist to visit on account of the richness of the flora, numerically speaking, and because of the assemblage in one geographical region of many species peculiar to a certain physical or meteorological zone. The aquatic flora, the Alpine flora, the desert and tropical floras, are all found associated within a radius of a few miles. Altitude and the distribution of the rainfall explain this somewhat interesting feature of the flora. The problems presented to the botanist for solution are very intricate, and it is necessary for him in order to solve the more difficult questions to spend considerable time in the field where the plants are to be found surrounded by natural conditions.

Each of the plant communities into which the flora of a country as vast as Mexico can be divided can be distinguished by the component plants which, together by their collective features, give character to the vegetation of a particular meteorological, geological or physical region of the earth's surface. Such a flora as the Mexican can be classified into several ecological* communities, as follows:

1. Hydrophytic Community, composed of Hydrophytes, or water-plants.

2. Xerophytic Community, composed of Xerophytes, or desert-plants.

3. Halophytic Community, composed of salt-loving plants.

4. Mesophytic Community, including those plants found in intermediate situations, such as plants of the tropical forests, palm forests, bamboo thickets, temperate deciduous forests, subtropical evergreen forests and plants of the Arctic, Alpine and prairie regions.

The valley of Mexico is especially suited

*Ecology is the study of plants with reference to their environmental conditions and covers the field of the so-called biology of plants.

to ecological inquiries. It is an elevated circular valley, closed in by two distinct ranges of hills, the oldest porphyritic rocks to the north and east, which before volcanic disturbances began sloped gradually southward toward the Isthmus, and the newer volcanic mountains to the south and west built up in a later period and closing off to the south and east the gradually sloping plain, thus forming the basin-shaped plateau known as the Valley of Mexico. Ajusco, the oldest volcanic peak, stands like a sentinel on the southern rim of the basin, and from its summit to the base of the valley extends a lava bed known locally as the Pedregal. On the southeast rim of the valley rises the ice-capped peak of Popocatapetl (17,780 feet), and to the eastward, connected with the conical volcano, the ridged backbone of Ixtaccihuatl, also snow-capped, considered by geologists to be built of the older porphyritic rocks. Along the base of the eastern range three fresh-water lakes, Texcoco, Chalco and Xochimilcho, are found, while the partially drained basin of lake Texcoco forms an alkaline plain stretching along the Mexican railroad to the hills which jut southward into the plain at Guadalupe.

The lakes and communicating ditches furnish the hydrophytes, the alpine summits of Popocatapetl, Iztaccihuatl and Ajusco (13,612 feet) the alpine plants; the lava beds afford a large number of xerophytes, while the alkali plain near lake Texcoco grows a number of halophytes which reach their greatest numerical development on the Gulf coast. The rich agricultural soil of the valley grows a varied and luxuriant series of mesophytes. It presents in its constricted area a veritable botanical garden, right at the doors of the population of the capital.

Space will not permit a detailed account of the plants found growing in the different vegetable zones. Only one or two plants can be taken by way of illustration. The xerophytes show very thick leaves, thick cuticle and a hairy or spiny covering, and are usually consolidated in structure. The plants are peculiarly constructed so as to store water by means of certain mucilaginous substances which absorb moisture and hold it tenaciously, giving it off very slowly to the air. The Agave, Maguey or Century-plant, commonly found cultivated on the plateau of Anahuac, is a typical xerophyte. It is to be seen growing wild in desert places and on lava beds, and grows in one or two forms to a large size (eight feet), weighing sometimes 600 to 800 pounds. It is a plant of considerable pharmaceutical interest. It stores up in its tissues a surprising amount of a sugary water, which exudes when the plant is tapped, as the so-called honey water or aguamiel. This aguamiel when fermented yields the beverage called pulqué, which is consumed in large quantities by the poorer Mexicans, who pay una cuartilla (3 cents Mexican, $1\frac{1}{2}$ cents American) for a glass of this yeasty-tasting alcoholic drink. It is obtained from the plant in the following way: When the Agave, which yields the liquid honey water, reaches adult size, turns slightly yellow and begins to shoot up a flower stock, or before that time, it is tapped by hollowing out a concavity in the core of the plant at the base of the central leaves, which stand upright and are not yet fully expanded. The pulqué-gatherer, with a long hollow gourd pierced at both ends, draws the aguamiel by suction from the concave place as it wells up from beneath. He is clad in cheap cotton clothes and wears a hide apron fastened around his waist and a thick leather knee pad on his left leg. Then pressing the spiny leaves aside with his left knee, he pushes one end of his gourd with his right hand into the tapped place and draws upon the other end with his mouth, until he has filled the

gourd with maguey liquid. He then transfers it to a vessel made of pottery reinforced by wicker work, or, as is the usual custom, he pours it into a vessel made of a hogskin. When his skin vessel is full he carries it to the shed, where for 36 hours the Agave juice is allowed to ferment, changing during this process from a yellowish-looking fluid to a milk-white, yeasty-looking fluid. It is a very refreshing and wholesome drink for those high altitudes, if taken in moderation. Drunkenness is the result of its too free use. It is laxative, and is reputed to be antiscorbutic, and through its assisting digestion quiets the heart's action. The best pulqué is obtained in country places, the writer finding its use refreshing and cooling, the city pulqué being inferior to that of the suburban towns, being watery and sour. Pulqué keeps its freshness but a day, when it begins to sour. The sour liquid is distilled and yields according to the process used two or three powerful alcohol drinks, mezcal, tequila and aguardiente de maguey. There are two or three beverages or soft drinks in use, one made from the pineapple and called piño, and another tepache might be termed sugar-cane cider. The latter drink, as a rule, is to be had along most of the country roads running from Mexico. The mezcal, tequila and aguardiente are very powerful in their effects. A Mexican Indian addicted to their use can drink a glass of any one of the three without effect; two or three glasses will set him demoniacally crazy.

The alpine flora is interesting on account of the dwarf, cespitose habit of the plants, their hairy covering and brilliantly colored flowers. The plants of this region are mostly perennial, very few annual plants being found in this zone. The lake flora is interesting, as the plants are distributed in the ditches and along the borders of the lagoons and lakes. *Eichornia crassipes*, the water hyacinth, *Marsilia heterophylla*, *Ruppia*, *Agenipea*, *Escobedea linearis*, *Polygonum amphibium*, *Nymphœa mexicana*, *Lobelia splendens*, and a water lily with white flowers and large leaves, are a few of the plants of the hydrophytic community.

The Chinampas, or floating gardens, are in lakes Chalco and Xochimilcho. At one time they really did float, but now they are anchored to the bottom by the roots of trees and form little patches of garden ground, separated by narrow canals. Here are grown flowers and vegetables for the city market The canoes of the Indians bring the produce to the city by the Viga Canal, where it is sold along the banks of the canal, or in the markets, the principal one of which is called the Volador, south of the National Palace and occupying a site that was included in the grounds of the 'new house' of Montezuma, and, therefore, after the Conquest was a part of the property of Cortez. Here are sold all manner of fruits and vegetables, apples, peaches, pears, pomegranates, mammees, figs, bananas, tunas, quinces, tomatoes, corn, beans and other agricultural products. The meat and poultry stalls are equally important, but it is to the sellers of herbs that a druggist would turn with most interest.

An old Indian woman, knitting or sewing, occupies a seat in an enclosed stall, surrounded on all sides by dried herbs and medicinal plants. For a small sum of money she will prescribe for all the ailments to which the flesh is heir, drawing upon her supplies of drugs hanging about the stall. These substances are compounded into medicine, according to her directions, and it seems that the peons have faith in her skill, for numbers of them were seen around the stall asking medical advice. Casually, while inspecting the market, hasty notes were made of a few of the remedies which composed her stock of drugs. There were panicles of *Sambucus mexicana*, dried flowers of *Datura arborea*, dried plants of

Achillea millefolia, a few Mammillarias, tops of *Datura* with stems and pods, dried gourds, bunches of unkown herbs wrapped in corn husk, bunches of the pepper tree (*Schinus*) *molle*, bunches of dried roots, sea beans (*Mucuna*), hoofs of a deer, ears of a donkey dried, stuffed birds, carapace of a turtle, dried alligator with skin removed, armadillo skins and other remedies too numerous to mention. I returned again and again to this market and always found it a source of information and amusement.

Mexico is a very rich and virgin field for ecological study and is yet an unworked field. Similar observations in other regions have been made by Dr. Eugene Warming, of the University of Copenhagen, several years ago in Venezuela; at Lagoa Santa, by Dr. Scott, who explored the Cape region of South Africa, in the Kalahari desert; by Professor Stahl in Java, and last year in Mexico; and by Professor Trelease, of the Missori Botanical Garden, on the Yuccas of the southwestern United States and northern Mexico.

JOHN W. HARSHBERGER.
UNIVERSITY OF PENNSYLVANIA.

BOTANY AT THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SECTION G organized on Monday, August 9th, at 12 m., with about 18 persons in attendance, the Vice-President and Secretary both being in their places. After the election of 3 fellows to serve on the Sectional Committee further elections were postponed till the following morning, when the full organization was completed. The attendance on the meetings ran up each day to about 50, except during the Vice-Presidential address, when the room was crowded with about 150 people. The list of new officers elected for the Section is found elsewhere in this JOURNAL, and need not be repeated here.

Two invitations given to the Section were quite generally accepted by its members; the one being to a visit of inspection to the immense pharmaceutical laboratory of Parke, Davis & Co., in Detroit; the other being to a trolley ride and entertainment by Mr. Joseph Berry, of Grosse Pointe, where the fine grounds, extensive gardens and conservatories were greatly enjoyed.

During its session the Section was honored with a brief visit from Professor H. Marshall Ward, of Cambridge University, England.

The papers read numbered a total of 26. Several of the older botanists usually in attendance at the meetings of the Association were absent, and there was, therefore, a predominance of younger members; the quality of papers was, however, good, the most of them being narrative of original research on the part of their authors.

The preliminary program has already been published in SCIENCE (pp. 222–223 above), and the following papers were subsequently entered:

'On a New and Improved Self-Registering Balance,' by Dr. Alex. P. Anderson.

'The Correlation of Growth under the Influence of Injuries,' by Dr. C. O. Townsend.

'The Botanical Collection of the Cornell Arctic Expedition of 1896,' by Professor W. W. Rowlee and K. M. Wiegand. [Read by title.]

'Description of *Bacillus Phaseoli* n. sp., with some Remarks on Related Species,' by Dr. Erwin F. Smith.

'On the Nature of Certain Pigments produced by Fungi and Bacteria, with special reference to that produced by *Bacillus solanacearum*,' by Dr. Erwin F. Smith.

Since the address of the Vice-President on 'Experimental Morphology' has been published in full in this JOURNAL, comment need not be given here, except to say that the address, illustrated by lantern-slides was a collaboration of results of many botanists in experimental morphology, and was full of suggestion for future research in this direction.

Professor Davis' paper on the variation of

Trillium grandiflorum was accompanied by numerous dried specimens presenting the most remarkably monstrous forms. There were forms without the usual leaves, but in which all the floral organs except stamens were transformed into green foliage; acaulescent forms, forms with petioles 12 cm. to 15 cm. long, petiolated sepals and petals, forms with doubled sepals and petals, and forms without any stamens or pistils. In one locality in eastern Michigan over 400 monstrous individuals were collected. Of all organs the stamens vary least; they usually contain pollen. The pistils are commonly without true ovules, bearing leafy outgrowths instead. The author did not attempt to explain the teratology, but suggested that it might be propagated by fertilizing normal forms with pollen from the monstrous ones. In the discussion which followed the reading of the paper, Dr. Smith reported making a similar collection of the same species near the same locality and reporting it in the *Botanical Gazette* fifteen or more years ago. The Vice-President queried whether a preceding burning over with fire might not call forth the teratological forms. It was stated, however, by several present that such forms had been found where fire had not occurred for many years. Mr. Day reported a constant variety from Goat Island, Niagara River. Professor Britton had had no reports of these variations from the Appalachian region.

Mr. Wiegand reported variations in the form of fruit in closely related species of Galium. In some species the fruit is saucer-shaped, in others cup-shaped, and in others the edge of the cup is so narrowly constricted as to leave but a pore connecting the hollow interior with the exterior.

Professor Bessey reported the progress of the Botanical Survey of Nebraska. The Survey was organized in 1892 by the Botanical Seminar of the University of Nebraska, since which time it has brought together more than 10,000 specimens; published 'Reports I., II., III. and IV.'; published 'Parts I., II. and XXI.' of the 'Flora of Nebraska.' The total number of species known to the State is about 3,400.

This same author considered the question of the retreat of trees from Nebraska plains, concluding that none are known to be receding, while several species, such as the bur-oak and the pines, are advancing.

Dr. Bessey also described the foot-hill vegetation of western Nebraska. The foot-hill region is an elevated plain 1,200 meters above sea-level, upon which are Pine Ridge on the north, 1,500 meters above sea-level, and Cheyenne Ridge on the south, 1,700 meters above sea-level. Upon Cheyenne Ridge occur considerable bodies of trees, mostly pines, with red-cedar, box-elder and others. The Box Butte plains are covered with a uniform grass-formation.

Mr. J. H. Schuette's extensive paper on wild and cultivated roses of Wisconsin was read in brief abstract by Professor Bessey, who expressed himself as of the opinion that the author should make a wider study of native roses in the United States before publishing.

Professor Beal's paper, denominated 'How Plants Flee from their Enemies,' consisted in the citation of numerous examples of plant distribution as affected by hostile external conditions.

The 'Bacteriosis of Carnations,' as reported by Mr. Woods, is not due to a bacterial disease, as has been supposed, but to the punctures of aphides and thrips. The cells affected become œdemic, collapse and give a whitish sunken spot. The dead tissue may subsequently become infested by bacteria and fungi.

Dr. Erwin F. Smith reported the corroboration of Wakker's claim that a certain disease of the hyacinth is caused by a bac-

terium. The author was able to produce the disease by inoculation in healthy plants. Owing to the care with which the Hollanders inspect their exportations the disease is unknown in this country.

Dr. Smith described another bacterium, *Bacillus Phaseoli*, with related species, showing that this organism is a serious disease of garden and field beans. Thermal and cultural relations were shown, likewise drawings, photographs and macroscopical preparations, all aiding in the identification of the species.

The same author discussed the relations of the brown color of humus soils to the pigment produced by *Bacillus solanacearum*, suggesting that this coloration of soils may be due to the action of bacteria in splitting up the carbohydrates of the humus. The isolated pigment will not serve as nutrient material for bacteria.

Mr. C. A. Peters' report of the formation of the reproductive organs of *Drosera* showed some details of pollen-origin and structure differing from those in most dicotyledons.

Dr. Schlotterbeck reported that according to his study the appendage to the seed of *Melampyrum pratense* is not a strophiole, nor a caruncle, nor an arillus, each of which has been claimed, but is a part of the endosperm which becomes constricted off from the rest during development. The same author has found the nucellus of *Croton Tiglium* protruding far out of the micropyle, the only other similar case known being that of *Croton flavens*.

In the development of the pollen of the common milkweed, *Asclepias cornuti*, Professor Spalding reported the work of Miss Langdon as showing some errors in the published account by Corry, especially regarding the origin of the pollen-mother-cells and the outer wall of the pollinia. Peculiar changes in the protoplasm of the tapetal cells were also discussed with reference to their physiological significance. In the discussion which followed, the question arose as to what cells are to be denominated pollen-mother-cells in this plant—whether the cells that by division into four give rise to the pollen-grains, or whether these four daughter-cells themselves are the pollen-mother-cells.

Dr. Anderson reported the discovery o stomata on the bud-scales of *Abies pectinata*. What gives peculiar significance to this discovery is the fact that heretofore stomata have been thought never to occur on the bud-scales of Gymnosperms.

The paper by the same author on the comparative anatomy of normal and diseased organs of *Abies balsamea* showed differences in structures of leaves of the lateral and erect branches; the presence of 2 to 6 resin canals in the bud-scales from which the resin, exuding through fringing hairs, spreads in a layer 1 to 3 mm. thick over the scale; the formation of resin-vesicles in the primary cortex by the growth of the epithelial lining to the resin canals.

Dr. Townsend's paper on the correlation of growth and injury narrated experiments with seedlings, larger plants and with *Phycomyces nitens*. The injuries were given by excising parts of the plant, or by incisions. In *Phycomyces* there was a sudden retardation of growth after cutting, and the normal rate was regained after 30 to 60 minutes. In higher plants there ensues on severe injury a gradual retardation, followed by a gradual regain of normal rate, a period of acceleration sometimes preceding. In seedlings, especially, a rather slight injury caused an acceleration in 6 to 24 hours, with a subsequent fall to the normal rate. The distance through which the injury may influence the rate of growth may amount to several hundred millimeters. The amount of variation in rate of growth may equal 80 % of the normal rate.

'The Mechanism of Root Curvature'

is a vexed question. Professor Spalding reported work done in his laboratory from which it would appear that not only one side of the root is concerned in producing the bending, but both sides. As a result of numerous experiments it is concluded that the effect of the stimulus is not altogether, as has been supposed, on cell-membranes, nor upon the activity of protoplasm in manufacturing osmotic material, but is manifested in a molecular change in the protoplasm by which it becomes more permeable to water. The tense membranes consequently contract, shortening the side that thus becomes concave. It is claimed that, at the same time, the effect of the stimulus is to increase the length of cells on the side becoming convex. An important difference between this theory and its predecessors is that this proposes to utilize the tensions usually existing in straight roots to account for the curving.

The action of a cellulose dissolving enzyme extracted from cotyledons of seedlings of *Lupinus albus* was described by Professor Newcombe.

Professor True's paper on the toxic action of phenols on plants aroused considerable commendation and discussion. It has been known quite generally that plants are very sensitive toward certain substances, so sensitive that they may be used as tests for certain compounds diluted far beyond the capacity for identification by the usual chemical means. A study of the toxic action of the group of substances known as phenols has shown that living organisms respond in a definite manner to substances having a definite constitution, the reaction of the protoplasm being thus far governed by chemical laws. Electrolytic dissociation of the molecules into ions plays a subordinate rôle in the physiological action of these compounds, the undissociated molecules, therefore, determining to a large degree the physiological properties of the substances. Certain radicles seem to have specific properties when introduced into the molecule, modifying the toxic value of the same.

Dr. Hart sought to prove that the acridity of the juice of *Arum* is not due, as claimed, to the mechanical action of the raphides. He exhibited preparations of the extracted juice which had been filtered and still preserved its acridity. He described also a series of experiments upon himself, detailing the physiological effects of the administration of the juice.

Dr. Anderson described a self-registering torsion balance—an improvement over the one previously described by him. This instrument will record the increase or decrease in weight of any object that can be placed upon the balance, changes of .5 gm. being sufficient to make a record.

In joint session of Sections F and G, Professor Osborn and Professor Poulton presented a theory harmonizing to some extent Darwinism and Lamarckism, which is published in the present number (page 583) of SCIENCE.

FREDERICK C. NEWCOMBE,
Secretary Section G.

ANTHROPOLOGY AT THE TORONTO MEETING OF THE BRITISH ASSOCIATION.

SECTION H was perhaps the best attended of all sections of the Association, the large West Hall of the University of Toronto, where the sessions were held, being filled on several occasions, while on Wednesday, August 25th, when the joint discussion with Section C (Geology) took place, standing room was at a premium. The chairmanship of Sir William Turner, the celebrated anatomist, who presided with grace, dignity and a broad-minded discrimination that won the admiration of all who were privileged to present papers or to take part in the various discussions which arose, was a

delightful feature of the meeting, while the frequent attendance of Sir John Evans constantly reminded those present that the science of anthropology was well honored in the illustrious President of the Association. American anthropologists were well represented at the meeting and on the program as well—Miss Alice Fletcher, Professor F. W. Putnam, Dr. W J McGee, Professor E. S. Morse, F. H. Cushing, Dr. A. F. Chamberlain, Stansbury Hagar, Professor L. Witmer, etc., represented the United States, and David Boyle, A. F. Hunter, Rev. John Maclean, Geo. Iles, Dr. G. M. Dawson, etc., Canada. Among the distinguished British members present or contributing to the program were: E. W. Brabrook (President of the Anthropological Institute); Professor A. Macalister, of Cambridge; Dr. R. Munro, the investigator of British lake-dwellings; E. S. Hartland, the folk-lorist; Professor A. C. Haddon, who has written of 'Evolution in Art;' Dr. H. O. Forbes, traveler and anthropologist; F. T. Elworthy, who has written of the 'Evil Eye;' Sir Geo. S. Robertson, 'the hero of Chitral;' F. C. Selous, the South African traveler. Altogether some fifty reports, papers, etc., were laid before the Section and two extended discussions on 'American-Asiatic Contact' and 'The First Traces of Man in America' took place. Of the papers read, eight were by Canadians, eleven by British members, eleven by members from the United States.

The officers of the Section were as follows, due recognition being given to American anthropologists, both in Canada and the United States:

SECTION H.—ANTHROPOLOGY.

President: Professor Sir W. W. Turner, M. D., LL.D., F.R.S.

Vice-Presidents: E. W. Brabrook, C.B., Pres. Anthr. Inst.; Professor A. Macalister, M.D., F.R.S.; Dr. W J McGee; R. Munro, M.D., F.R.S.E.; Professor F. W. Putnam, D.Sc.

Secretaries: A. F. Chamberlain, Ph.D.; H. O. Forbes, LL.D.; Professor A. C. Haddon, D.Sc.; J. L. Myres, M.A., F.S.A. (*Recorder*).

Committee: F. H. Cushing; David Boyle; Dr. G. M. Dawson, C.M.G.; F. T. Elworthy; A. F. Hunter; Professor E. S. Morse; E. Sidney Hartland, F.S.A.; Professor Lightner Witmer, Ph.D.

Owing to the conservative regulations of the Association, Miss Alice Fletcher, being a woman, could not receive the official honor unanimously voted her by the Section Committee, who, however, by assigning her the first place on the program, paid a graceful compliment to her scientific attainments, which, together with the chairman's well-worded encomium at the conclusion of her address, was a tribute which an antiquated idea of scientific *personnel* utterly failed to minimize.

In detail the program was carried out as follows:

THURSDAY, AUGUST 18.

1. *The Scalp-Lock, A Study of Omaha Ritual.* MISS ALICE C. FLETCHER.
2. *The Import of the Totem Among the Omahas.* MISS ALICE C. FLETCHER.

In these two papers were contained remarkably clear presentations of the problems of what might, perhaps, be called 'the higher life' of the Omaha Indians, the general ideas and ideals which underlie the hair-cutting ceremonial and the institution of the totems being carefully explained and accidental or incidental phenoma rated at their true value. That the acquisition of the totem represented the outburst of individuality and personality on the part of the young Indian was ably shown, and the relations of personal, gentile and tribal totems elucidated.

The discussion following the paper was

shared in by Sir Wm. Turner, Dr. McGee, Mr. E. S. Hartland, F. C. Selous, all with warm appreciation of the ability of the author in her treatment of a very difficult subject. Dr. McGee emphasized the artificiality of certain social phenomena of primitive peoples. Mr. Hartland pointed out the great value of the proper interpretation of the ideas and institutions of the lower races.

3. *Squaktktquacht, or the Benign-Faced, the Oannes of the Ntlakapamuq, of British Columbia.* B. HILL-TOUT.

This was a detailed version of the 'younger brother' tale of the Ntlakapamuq, a Salish tribe of southern British Columbia. The 'Benign-faced' is culture-hero, animal-transformer, fish-befriended, wizard-destroyer, etc.

4. *The Blackfoot Legend of Scarface.* R. N. WILSON.

5. *Blackfoot Sun Offerings.* R. N. WILSON.

The first of these interesting papers told the adventures of 'Scarface,' a young Indian, whose personal disfigurement caused the maiden of his heart to refuse her hand in marriage until the scar on his face should be removed. After much wandering 'Scarface' accomplished this by the help of the sun (whose lodge he visited), the moon and the morning-star. Returning to earth, he received, in due time, his beloved, and instituted the system of offerings to the sun, of which a detailed account was given in the second paper.

6. *Star-Lore of the Micmacs of Nova Scotia.* STANSBURY HAGAR.

In this essay valuable details were given of the stellar Eden of the Micmacs, their lore of the Pleiades, moon and sun, the heaven-birds, etc.

7. *The Lake Village of Glastonbury and its Place Among the Lake Dwellings of Europe* (lantern illustrations). DR. R. MUNRO.

In this well-illustrated lecture the importance and the great extent of lacustrine remains in Europe were clearly demonstrated and the need for further explorations emphasized.

8. *Report on the Silchester Excavations.*

A brief account (a full report of the antiquities on exhibition at Burlington House is given in 'Archæologia,' Vol. LV., pp. 409–430) of the investigations carried on since 1896 on the site of the Roman city at Silchester.

9. *Some Old-World Harvest Customs* (lantern illustrations). F. T. ELWORTHY.

Illustrative account of the development and variations of the 'Kern-maiden,' and associated apparatus.

10. *Report on the North Dravidian and Kolarian Races of Central India.*

'No further progress' was reported in the transcribing and translating of Mr. Raynbird's extensive collections on the linguistic and anthropological characteristics of these peoples.

FRIDAY, AUGUST 20.

11. *Some Distinctive Characters of Human Structure* (lantern illustrations). The President's address, Sir W. W. TURNER.

The essence of this most admirable and eloquent address, to which a crowded hall listened with rapt attention, is contained in the following extract:

"We know that an animal is guided by its instincts, through which it provides for its individual wants, and fulfills its place in nature. In man, on the other hand, the instinctive acts are under the influence of the reason and intelligence, and it is possible that the association centers, with the intermediate association fibers which connect them with the sensory and motor centers, may be the mechanism through which man is enabled to control his animal instincts, so far as they are dependent on motion and sensation.

"The higher we ascend in the scale of humanity the more perfect does this control become, and the more do the instincts, emotions, passions and appetites become subordinated to the self-conscious principle which regulates our judgments and beliefs. It will, therefore, now be a matter for scientific inquiry to determine, as far as the anatomical condition will permit, the proportion which the association centers bear to the other centers, both in mammals and in man, the period of development of the association fibers, in comparison with that of the motor and sensory fibers in different animals, and, if possible, to obtain a comparison in these respects between the brains of savages and those of men of a high order of intelligence.

"The capability of erecting the trunk, the power of extending and fixing the knee joints when standing, the stability of the foot, the range and variety of movement of the joints of the upper limb, the balancing of the head on the summit of the spine, the mass and weight of the brain and the perfection of its internal mechanism, are distinctively human characters. They are the factors concerned in adapting the body of man, under the guidance of reason, intelligence, the sense of responsibility and power of self-control, for the discharge of varied and important duties in relation to himself, his Maker, his fellows, the animal world and the earth on which he lives."

The address was illustrated with numerous lantern-slides which served to render perfectly intelligible some of the more intricate anatomical points involved in the comparative study of the anthropoids, the human young and the various races of men.

12. *A Demonstration of the Utility of the Spinal Curves in Man.* PROFESSOR ANDERSON STUART.

By means of a most ingenious machine, in which were a straight brass rod and a curved one, made so as to be subject to concussion, Professor Anderson Stuart showed what would have been the result had the human spine been perfectly straight. The skull would have been broken.

13. *The Causes of Brachycephaly.* PROFESSOR A. MACALISTER.

14. *Notes on the Brains of Some Australian Natives.* PROFESSOR A. MACALISTER.

After noting the great prevalence (seemingly irrespective of race) of brachycephaly among infants, Professor Macalister emphasized the importance of brain-growth as a determining factor in head form; the increased bulk of the frontal lobes, which grow most rapidly and largest in the higher races, causes brachycephaly. Photographs of Australian brains were exhibited and explained to illustrate the points of difference between savage and civilized man.

15. *On Some Uses of Trepanning in Early American Skulls.* DR. W J MCGEE.

By means of an exhibit of pre-Incan Peruvian skulls, Dr. McGee discussed and explained the nature, process and probable uses of trepanning, the implements employed and the probable causes of the incisions. About 50% seemed cases of survival, but he did not care to credit the old Peruvians with very great surgical knowledge. Trepanning began in the taking of trophies; the head dwindled to a piece cut out of the skull, and passing through vicarious and sortilegic stages reached a stage of more or less blundering surgery.

In the discussion which followed the reading of the paper, Sir W. W. Turner seemed inclined to rank higher the surgical skill of the ancient Peruvians, and Professor Macalister stated that out of 87 Peruvian skulls he had examined two were trepanned, approximately the same number (2%) as Dr. McGee had found.

16. *Mental and Physical Deviations from the Normal Among Children in the Public Ele-*

mentary and Other Schools. Report (by DR. FRANCIS WARNER, Secretary of the Committee).

This fifth annual report of the committee 'gives an account of 1,120 children who appear to require special care and training, as being sub-normal in their mental or physical status.' The report is accompanied by many detailed tables. It is the intention of the committee to act in future with the recently formed 'Childhood Society,' of which the Earl of Egerton and Tatton is President and Sir Douglas Galton, Chairman.

17. *Report on Anthropometric Measurements in Schools.*

The work done by the committee during the past year has 'consisted solely in the distribution to applicants of the rules for measurement drawn up by the committee, and in advising those responsible for physical measurements in schools as to points respecting which they had written for advice.'

18. *The Growth of Toronto School Children.* DR. FRANZ BOAS.

This paper summarized the results of the extensive measurements of Toronto school children made in 1892, under the superintendence of Dr. A. F. Chamberlain. The chief points brought out were: American (Oakland, California) children are slightly taller than Canadian (Toronto); first-born children are somewhat taller than later-born children; families in Toronto are larger than those in Oakland; the families of Canadian descent are smaller than those in which the grandparents are of English birth.

In the discussion on this paper Professor Brabrook and Dr. A. F. Chamberlain took part, both emphasizing the importance of social atmosphere and environment in connection with physical well-being.

19. *An Experimental Analysis of Certain Correlations of Mental and Physical Reactions.* PROFESSOR LIGHTNER WITMER.

Professor Witmer, illustrating his remarks by numerous charts, discussed the differences in muscle tone, the rôle of the mental factor in physical processes, the sexual and racial differences in quickness of movement, etc.

In the discussion following the paper Professor A. C. Haddon, Dr. A. F. Chamberlain, Mr. David Boyle, all expressed their desire for a uniform system of mental and physical measurements, to be used in both the Old World and the New.

20. *Anthropological Work in the New York Pathological Institute.* DR. HRDLICKA.

In this paper Dr. Hrdlicka sketched the history, the prospects and the desirabilities of the anthropological department recently established in the New York Pathological Institute, as well as the system of investigation employed.

21. *The Physical Characteristics of European Colonists born in New Zealand.* DR. H. O. FORBES.

22. *A Case of Trepanning in New Mexico.* CARL LUMHOLTZ and DR. HRDLICKA. Read by title.

MONDAY, AUGUST 23.

23. *Report of the Committee on the Northwestern Tribes of Canada.* DR. FRANZ BOAS.

This was a summary of the work done under the auspices of the committee during the past twelve years in investigating the physical characters, languages and industrial and social conditions of the northwestern tribes of the Dominion of Canada.

In the discussion Professor Brabrook, Dr. A. F. Chamberlain, Professor E. C. Haddon and Rev. John Maclean took part, the evil of governmental interference with native tribes being pointed out.

24. *The Seri Indians of the Gulf of California.* DR. W J MCGEE.

A most interesting account was given of the Seri Indians, perhaps the most primitive of all American aborigines—autocthones, if there be any such in the New World; their arts and institutions, their fine physique, skill in hunting, their stone art, shell mounds, etc., were noted and described.

25. *Notes Historical and Philological on the Indians of British Columbia.* C. HILL-TOUT. Read by title.

26. *The Kootenays of British Columbia and their Salishan Neighbors.* DR. A. F. CHAMBERLAIN.

27. *Kootenay Indian Drawings.* DR. A. F. CHAMBERLAIN.

In the first paper the author discussed the relation of the Kootenays—whose language forms a distinct stock—to their Salishan neighbors on the west, the Shushwap. The Kootenay speech contains a few Salishan words; the animal tales of both peoples have many resemblances; the manufacturing arts are alike sometimes in detail. But the most remarkable contact-phenomena is the possession by both these peoples of the peculiar double (downwards) pointed canue, of what Professor Mason calls the Amoor type.

The second paper was devoted to the explanation of some 300 drawings—natural objects, men, animals, instruments, etc.—made by the Kootenay Indians, and the consideration of their resemblances to, and their differences from, the drawings of children. The keen observation gift of the Indian, the greater truth to nature, the longer time taken to draw them, all evidence the differences between these primitive art products and the cruder, ruder efforts of children.

In the discussion Sir William Turner and Professor Haddon called attention to the importance of such collections of primitive art, as also did Dr. Munro, who pointed out the necessity of such data for comparison with the art of early man in Europe.

28. *A Rock Inscription on Great Central Lake, Vancouver Island.* J. W. MACKAY.

Brief description, accompanied by photograph, of symbolic rock-carving of a tree.

29. *Blackfoot Womanhood.* REV. J. MACLEAN.

A detailed account of woman's life, arts, influence, etc., among the Blackfoot Indians of Canada. The Indian legends as to the creation of woman—she was made first—her sociological status, the influence of mythology and religion, the division of labor, marriage-customs, result of contact with civilized races, were touched upon. Some traces of 'woman's language' were found. The merry laughter of the women is noticeable.

30. *On the Hut-Burial of the American Aborigines.* E. SIDNEY HARTLAND.

An extended ethnographic account of burial within the hut as practiced by the American Indians. According to Mr. Hartland, 'Its origin must be sought for in the savage idea of kinship, and in the desire to retain within the kin the deceased, with all his powers and virtues.'

31. *Report on the Ethnological Survey of Canada.*

The first report of the committee appointed at the Liverpool meeting, 1896, suggesting subjects and lines of investigation of native and intrusive races of the Dominion.

32. *Origin of the French Canadians.* B. SULTE.

A brief account of the chief groups of early French settlers in Canada and their places of origin. Mr. Sulte notes a 'remarkable uniformity of language among the French Canadians'—a point regarding which there is still some dispute.

33. *Report on the Ethnographic Survey of the United Kingdom.*

The chief portion of the report was an extended folk-lore collection by the late Dr. Gregor.

In connection with the report Professor Macalister gave an interesting résumé of anthropometric data procured by him and Professor Haddon from the scientists on the Parisian, who kindly submitted to these measurements.

34. *The Evolution of the Cart and Irish Car* (lantern illustrations). PROFESSOR A. C. HADDON.

By means of excellent slides the author showed the various stages in the development of the body and the wheels of the cart and the Irish car, and demonstrated how its retention was a matter of adaptation to the soil rather than of extreme conservatism. In the discussion which followed, many members took part and the wide prevalence of solid wooden wheels and other primitive cart elements was made evident.

TUESDAY, AUGUST 24.

35. *The Jesup Expedition to the North Pacific Coast.* PROFESSOR F. W. PUTMAN.

The first part of the morning session had been set apart for the discussion of 'Evidences of American-Asiatic Contact' and the subject was introduced by Professor Putnam, who, after giving an account of the origin of the Jesup expedition now exploring the North Pacific Coast, under the auspices of the American Museum of Natural History, New York, gave at some length his reasons for believing in the contact under discussion. Professor Putnam refused to believe that the aborigines of America belonged to one and the same race, and was inclined to mark off the culture races of Mexico, Central and South America and the Mound Builders from the North American Indians. The Eskimo of East Greenland were perhaps métis with early paleolithic man; the Caribs suggested an Africo-Mediterranean origin. The art of Central America, too, was suggestive of Mongolian contact.

The discussion on the paper was begun by Professor E. S. Morse, who at some length discussed the evidence so far brought forward of culture influencing contact between the peoples of America and those of Asia, concluding that the very ancient civilization of China and the adjacent countries had never penetrated to the New World. From a comparative study of the two world-civilizations such contact appeared not to be proved. Mr. F. H. Cushing, from his investigations of the arts, games, etc., of the Zuñis was led to the same conclusion, that the American peoples unaffected by cultural influences from Asia had been working out their own destiny. Dr. A. F. Chamberlain expressed his belief in the unity of the American race and the absence of any clear proof of cultural contact.

36. *Why Progress is in Leaps.* GEO. ILES.

Taking the mastery of electricity and the invention of photography and all the improvements and useful discoveries which have followed in their train, Mr. Iles indicated the rôle these factors play in the increased acceleration of human progress, making a day with us more than a thousand years with our ancestors. Such things are multipliers of, not additions to, human genius.

37. *Note on the Transmission of Acquired Characters* (lantern illustrations). PROFESSOR J. C. EWART.

An account of the foal of an Arab mare, supposed to be infected by the zebra sire of her first foal.

38. *The Kafirs of Kafiristan* (lantern illustrations). SIR GEORGE ROBERTSON.

An interesting account of a people whose Greek physiognomy has been noted by more than one observer. Their bridge-building, wall-decorations, tombs, the sphere of woman, etc., were discussed.

39. *The Mangyans and Tagbanuas of the Philippine Islands* (lantern illustrations). PROFESSOR DEAN C. WORCESTER.

Professor Worcester described, with considerable detail, two very primitive tribes of the Philippines, the Mangyans, of Mindoro, and the Tagbanuas, of Palawan. Their physical characteristics, manners and customs, arts, etc., were treated of. Very interesting was the author's account of the childish temperament of the Mangyans and their actions when a mirror was given them; likewise their inability to recognize representations of themselves in a picture. The lowland people were less physically well developed than the mountaineers, and the result of contact with the Spaniards was bad for both. They have no belief in a future state. Concerning the Tagbanuas, the following points are noteworthy: Child-marriage, the precocity of children, belief in a subterranean heaven, love of music, use of a syllabic alphabet.

40. *Report on the Necessity of the Immediate Investigation of Anthropology of Oceanic Islands.*

Professor Haddon, in presenting the report, emphasized the necessity for investigation of rapidly disappearing flora and fauna and tribes of men who will soon be gone forever. This is much more important than the study of other phenomena whose number is practically unlimited, whose existence is practically perpetual. Every year is a year lost.

WEDNESDAY, AUGUST 25.

41. *The Trenton Gravels.* PROFESSOR F. W. PUTNAM.

42. *Human Relics in the Drift of Ohio.* PROFESSOR E. W. CLAYPOLE.

The first hours of the session were devoted to a joint discussion with Section C (Geology) on 'The First Traces of Man in the New World,' introduced by the two papers just mentioned.

Professor Putnam gave a résumé of the investigations in the Trenton Gravels and of the evidence which led him to believe in the existence of paleolithic man in northeastern America, laying great stress on the existence of argillite implements in the gravel.

Professor E. W. Claypole described the finding of a grooved stone axe in stiff clay near the bottom of a well during the digging of it. The find came from the great glacial plains of northern Ohio. The evidence, however, is not entirely convincing, as all who shared in the discussion took occasion to observe.

The discussion was begun by Sir John Evans, who declared that the Trenton implements were of a decidedly neolithic form, and declined to believe in the existence of paleolithic implements in America comparable to those of the river-drift of England and France. He rather favored a vast extension of its neolithic period in America.

Dr. J. W. Spencer gave his geological opinion as to the age of the Trenton gravels anywhere from 5,000 to 50,000 years.

David Boyle stated that there was no evidence as to the existence of man in Canada during or immediately after the glacial period.

Professor E. S. Morse was rather more favorable than the others to Professor Putnam's contention. Dr. W J McGee, while admitting the presumption that man was very ancient in America, advised conservatism in the matter of early man, and suggested that the argillite objects found in the Trenton talus may be quite modern, the product of the present Indian stock. Neither here nor in Ohio is the evidence convincing. A great mass of evidence to which constant and repeated appeal can be made by anyone at any time is the great necessity here.

43. *Exhibition of Lance-headed Implements of Glass from Northwest Australia.* Sir W. W. TURNER.

44. *The Genesis of Implement-Making.* F. CUSHING.

Starting with the arboreal, artless precurser of man in southeastern tropical Asia, Mr. Cushing traced his development and extension after the acquisition of a larger brain, of the power to use the hand, of speech, etc., emphasizing the rôle of the psychic factor—the rule of the ideal instead of the physical, and the influence of seashore residence on primitive man. The passage from teeth and nails to shells and the passage of man through the pre-lithic and proto-lithic periods was indicated with numerous illustrative experiments and references to the investigations of the shell-heaps of Florida and Maine. It was a great triumph for man when he ceased to be a mere user of tools and came to make tools with tools.

45. *Adze-Making in the Andaman Islands* (lantern illustrations). PROFESSOR A. C. HADDON.

Professor A. C. Haddon exhibited a series of slides from photographs taken by Mr. Portman, showing the natives of the Andaman Islands in the various stages of manufacturing their adzes. It was a model series of anthropological photographs.

In the number and nature of the papers read, the discussions which followed them and the interchange, after the sessions were over, of thought and suggestions, the session was one of the most successful in the history of the Association.

The grants for anthropological research made by the General Association were as follows, the committees marked * having been reappointed:

* Tylor, Professor E. B.—Northwestern Tribes of Canada	£ 75	0 s.
* Munro, Dr. R.—Lake Village at Glastonbury	37	10
* Brabrook, Mr. E. W.—Ethnographical Survey (and unexpended balance in hand)	25	0
* Evans. Mr. A. J.—Silchester Excavation	7	10
* Dawson, Dr. G. M.—Ethnological Survey of Canada	75	0
Turner, Sir W.—Anthropology and Natural History of Torres Strait	125	0

A. F. CHAMBERLAIN.

---

*ORGANIC SELECTION.**

THIS discussion was held before a joint afternoon session of the Zoological and Botanical Sections. At the close of Professor Poulton's paper he was obliged to withdraw. The question of the inheritance of acquired characters was taken up by Professor Theodore Gill, and a few remarks were made by Professor C. E. Bessey and others upon the botanical side.

Professor Osborn introduced the subject by a brief history of the progress of thought in recent years, dwelling especially upon the fact that ten years ago all the leading Darwinians had strenuously adhered to the original view of Darwin, that 'fortuitous variation' plays the most important part in the origin of new types, and that there was little evidence for 'determinate variation.' He continued as follows: The evidence for definite or determinate variation has always been my chief difficulty with the natural selection theory, and my chief reason for giving a measure of support to the Lamarckian theory. This evidence has steadily accumulated in botanical and zoological as well as paleontological researches, until it has come to a degree of demonstration where it must be reckoned with.

Quite in another field, that of experimental embryology and zoology, the facts of adaptation to new and untoward circumstances of environment have begun to

* A discussion introduced by Professor Henry F. Osborn and Professor Edward B. Poulton at the Detroit meeting of the American Association, Wednesday, August 11th.

constitute a distinct and novel series of problems. In many cases they are so remarkable and so unexplainable that certain German writers, such as Driesch, have taken the ground that they spring from the ultimate constitution of living matter and are incapable of analysis. At the same time it has been recognized that these adaptations are purely individual, transitory or ontogenic, leaving for a long time, at least, no perceptible influence upon the hereditary constitution of the organism. What may be called the 'traditional' side of these adaptations impressed itself strongly upon Professor James Mark Baldwin in his studies of mental development, also upon Professor Lloyd Morgan in his studies of instinct. The latter, moreover, was one of the first among English selectionists to consider 'determinate variation' as a fixed problem which must be included in any evolution theory. Thus, independently, Professors Baldwin and Morgan and myself put together the facts of individual adaptation with those of determinate variation into an hypothesis which is in some degree new. The first illustration which I used was that of the creation of an 'arboreal man' out of any present terrestrial race by the assumption of an exclusively tree life. This life would be profound in its influences upon each generation producing what would be pronounced by zoologists a distinct specific type. In course of many thousand years such a type might become hereditary by the slow accumulation of arboreal adaptive and congenital variations. The basal idea of it was contained in the Romanes Lecture by Weismann, but it was not brought out with emphasis, nor subsequently developed by that distinguished author.

The position taken by Poulton, Morgan and Baldwin that individual adaptation is in itself a result of natural selection cannot be demonstrated, except in cases where it is evident that such adaptation is in response to revived ancestral experience. In many instances, individual adaptation, as in cases of regeneration, is of advantage to the individual, but decidedly detrimental to the race, where it would result in the perpetuation of the progeny of a maimed or imperfect embryo.

Organic selection is the term proposed by Professor Baldwin and adopted by Professor Morgan and myself for this process in nature which is believed to be one of the true causes of definite or determinate variation. The hypothesis is briefly as follows: That ontogenetic adaptation is of a very profound character. It enables animals and plants to survive very critical changes in their environment. Thus all the individuals of a race are similarly modified over such long periods of time that very gradually congenital or phylogenetic variations, which happen to coincide with the ontogenetic adaptive variations, are selected. Thus there would result an apparent but not real transmission of acquired characters.

This hypothesis, if it has no limitations, brings about a very unexpected harmony between the Lamarckian and Darwinian aspects of evolution, by mutual concessions upon the part of the essential positions of both theories. While it abandons the transmission of acquired characters, it places individual adaptation first, and fortuitous variations second, as Lamarckians have always contended, instead of placing survival conditions by fortuitous variations first and foremost, as selectionists have contended.

This hypothesis has been endorsed by Alfred Wallace. It appears to me, however, that it is subject to limitations and exceptions which go far to nullify its universal application. This is especially seen in the fact that the law of determinate variation is observed to operate with equal

force in certain structures, such as the teeth, which are not improved by individual use or exercise, as in structures which are so improved. A very large class of determinate variations in other stationary characters, such as the inner parts of the skull, also remain unexplained. My study of teeth in a great many phyla of Mammalia in past times have convinced me that there are fundamental predispositions to vary in certain directions; that the evolution of the teeth is marked out beforehand by hereditary influences which extend back hundreds of thousands of years. These predispositions are aroused under certain exciting causes and the progress of teeth development takes a certain form converting into actuality what has hitherto been potentiality.

Edward B. Poulton, M. A., F. R. S., Hope Professor of Zoology in the University of Oxford, continued the discussion. He began by saying that it must be admitted that the adaptation of the individual to its environment during its own life-time possesses all the significance attributed to it by Professor Osborn, Professor Baldwin and Professor Lloyd Morgan. These authorities justly claim that the power of the individual to play a certain part in the struggle for life may constantly give a definite trend and direction to evolution, and that, although the results of a purely individual response to external forces are not hereditary, yet indirectly they may result in the permanent addition of corresponding powers to the species, inasmuch as they may render possible the operation of natural selection in perpetuating and increasing those inherent hereditary variations which go further in the same direction than the powers which are confined to the individual.

Professor Osborn's metaphor in opening this discussion puts the matter quite clearly and will be at once accepted by all Darwinians. If the human species were led by fear of enemies or want of food to adopt an arboreal life all the powers of purely individual adaptation would be at once employed in this direction and would produce considerable individual effects. In fact, the adoption of such a mode of life would at first depend on the existence of such powers. In this way natural selection would be compelled to act along a certain path, and would be given time in which to produce hereditary changes in the direction of fitness for arboreal life. These changes would probably at first be chiefly functional, as Mr. Cunningham has argued (in the Preface to his Translation of Eimer). On these principles we can understand the arboreal kangaroo (Dondrolagus) found in certain islands of the Malay Archipelago, which is apparently but slightly altered from the terrestrial forms found in Australia. Professor Osborn has alluded to the arboreal habits said to have been lately acquired by Australian rabbits; these and the similar modifications in habits of West Indian rats are further examples of individual adaptive modification which may well become the starting point (in the sense implied above) of specific variation led by natural selection in the definite direction of more and more complete adjustment to the necessities of arboreal life. Although this conclusion seems to me to be clear and sound, and the principles involved seem to constitute a substantial gain in the attempt to understand the motive forces by which the great process of organic evolution has been brought about, I cannot admit that the importance of natural selection is in any way diminished. I do not believe that these important principles form any real compromise between the Lamarckian and Darwinian positions, in the sense of an equal surrender on either side and the adoption of an intermediate position. The surrender of the Lamarckian position seems to me complete,

while the considerations now advanced only confer added significance and strength to Darwinian standpoint.

I propose to devote the remainder of the time at my disposal in support of the conclusion that the power of individual adaptation possessed by the organism forms one of the highest achievements of natural selection, and cannot in any true sense be considered as its substitute. Professor Baldwin and Professor Lloyd Morgan thoroughly agree with this conclusion and have enforced it in their writings on organic selection. The contention here urged is that natural selection works upon the highest organisms in such a way that they have become modifiable, and that this power of purely individual adaptability in fact acts as the nurse by whose help the species, as the above-named authorities maintain, can live through times in which the needed inherent variations are not forthcoming, but in part acts also as a substitute, not indeed for natural selection, but for the ordinary operation by which the latter produces change. In this latter case natural selection acts so as to produce a plastic adaptable individual which can meet any of the various forces to which it is likely to be exposed by producing the appropriate modification, and this, it is claimed, is in many instances more valuable than the more perfect, but more rigid, adjustment of inherent variations to a fixed set of conditions.

A good example of the eminent advantages of adaptability in many directions over accurate adjustment in fewer directions is to be found in a comparison between the higher parts of the nervous system in insects and birds. The insect performs its various actions instinctively and perfectly from the first. It is almost incapable of education and of modifying its actions as the result of the observation of the effects of some new danger. It would appear that the introduction of the electric light can only affect the insects which are most attracted to it, by the gradual operation of natural selection. In the clothes-moths, which infest our houses, we may see an example of this; for these insects seem to be comparatively indifferent to light. Birds, on the other hand, have the power of learning from experience, of reasoning from the results of observation. At first terrified by railway trains, they learn that they are not dangerous, and cease to be alarmed; while the effect of fire-arms results in their increased wariness.

If this view of individual adaptability as due to natural selection be not accepted, it may be supposed that the individual modifications are due either to the direct action of the external forces or to the tendencies of the organism. But it is impossible to understand how the mechanical operation of such forces as pressure, friction, stress, etc., continued through a lifetime, could evoke useful responses, or why the response should just attain and then be arrested at a level of maximum efficiency. The other supposition, that organisms are so constituted that they *must* react under external stimuli by the production of new, useful characters, or the useful modification of old ones, seems to me to be essentially the same as the old 'innate tendency toward perfection' as the motive cause of evolution—a conception which is not much more satisfactory than special creation itself. The inadequacy of these views is clearly shown when we consider that the external forces which awake response in an organism generally belong to its inorganic (physical or chemical) environment, while the usefulness of the response has relation to its organic environment (enemies, prey, etc.). Thus one set of forces supply the stimuli which evoke a response to another and very different set of forces. We can, therefore

accept neither of the suggestions which have been offered. Useful individual modifications are not directly due to the external forces, and are not due to the inherent constitution of the organism.

The only remaining hypothesis is that which I have already mentioned—the view that whenever organisms react adaptively under external forces they do so because of special powers conferred on them by natural selection. This hypothesis will, it seems to me, meet and satisfactorily explain all the facts of the case, whether employed as a preparation or as a substitute for hereditary variations accumulated by natural selection.

ASTROPHYSICAL NOTES.

In the August number of the *Astrophysical Journal* Sir William and Lady Huggins publish a paper, read before the Royal Society in June, which throws light upon the perplexing behavior of the H and K lines of calcium in solar and stellar phenomena. It was early noted by Young that these lines were especially conspicuous in the spectrum of the solar chromosphere and prominences, while other calcium lines, strong in the ordinary solar spectrum, were seldom seen as bright lines. Recent researches with the aid of photography, chiefly by Hale, have still more emphasized the significant part played by these two radiations in chromosphere, prominences and faculæ. They rival those of hydrogen and helium in their prevalence and in the high elevations in the solar atmosphere in which they occur. It has therefore been the thought of many that possibly they are not due to calcium after all, but to some lighter gaseous element, existing as an undetected impurity in calcium, a view which after the discovery of argon in nitrogen would appear as not wholly unreasonable. Others have agreed with the opinion of Lockyer that at the excessive solar temperature the spectrum of calcium would become simplified so as to consist of but few lines, chiefly H and K, perhaps due to 'dissociation.'

The Huggins experiments now indicate, however, that the density is the determining factor, and they have succeeded in photographing in the laboratory a spectrum of calcium consisting solely of the H and K lines, with perhaps an analogous pair in the far ultra-violet region. This important result had hitherto not been accomplished by other investigators (although in retrospect, perhaps, it will appear that such plates have accidentally been secured), chiefly because the effort has been to use a spark of as high intensity as possible. The procedure now adopted consisted in taking the spectrum of a spark of feeble intensity passing between platinum electrodes which had been moistened with a solution of calcic chloride. Several *Ca* lines were present, but relatively to H and K the other lines were less intense than when electrodes of metallic calcium had been employed. On reducing the amount of calcium vapor present in the spark by successive washings of the electrodes in pure water the other lines retired, finally leaving only H and K.

These new results are confirmatory of the present view as to the extreme rareness of the vapors in the upper chromosphere, and may prove of much value in giving a criterion of the density of stellar atmospheres in the spectra of which the calcium lines appear in some of their different phases.

In connection with the approaching dedication of the Yerkes Observatory, which will occur on October 21st and 22d, a series of conferences will be held (from October 18th to 21st) which promise to be of much interest to astrophysicists. An extensive

program of papers and informal talks by numerous astronomers and physicists has been arranged, and experimental demonstrations are to be given of certain important recent discoveries, such as the effect of pressure upon wave-length, the application of interference methods to astronomical measurements, the effect of a magnetic field on radiation, etc.

Many celestial objects and the solar phenomena are also to be shown with the forty-inch Yerkes refractor.

E. B. F.

NOTES ON INORGANIC CHEMISTRY.

FROM an article in the *Eisenzeitung* on the output of platinum in Russia, we take the following notes: The Russian production of platinum is forty times greater than that of all other lands together. In Russia it is found exclusively in the southern Oural region. It is shipped in its crude state to Germany and there refined. (This statement is surprising, as it has been commonly supposed that most, at least, of the Russian platinum is worked up by Johnson, Matthey & Co., of London.) The output in 1895 was 4,413 kilos as against 2,946 kilos in 1880. The cost of crude platinum in Russia is at present about $216 per kilo. The amount of iridium found with the platinum is very small, being in 1895 only 4.1 kilos, in 1894 only slightly more than this.

IN the *American Journal of Science*, E. T. Allen describes several specimens of native iron from the coal measures of Missouri. They consisted of small grains, massed together in one instance in a calcareous sandstone, and in the others in a shale. Both sandstone and shale contained iron, and in two instances the grains were in close proximity to coal seams. The metallic iron in each case was quite pure and contained no nickel, and is considered to be undoubtedly of terrestrial origin.

IN the *Journal* of the Russian Physico-Chemical Society, G. P. Czernik gives an account of the investigation of the gases contained in two minerals from the Caucasus, a titaniferous cerite and a coal from Tkwibulsk containing in its ash 10 per cent. of the oxides of cerium, lanthanum and didymium. The former contains 1.1 per cent. of gases, chiefly argon, with a little oxygen and hydrogen. By heating to a red heat only one-fourth of the argon was liberated, by the action of 25 per cent. sulphuric acid at 60° rathar more than one-half. Much more was given off by fusion with potassium bisulphate. The author from this concludes that the argon is in chemical combination. The second mineral contains helium, which is liberated by fusion with potassium bisulphate, even after the ash has been heated to a white heat. Here, too, the inference is that the helium is in chemical combination.

THE *Bulletin* of the Pharmaceutical Society of Bordeaux, for July, contains an article by Dion on the formation of the fossil phosphate deposits of the Province of Oran. He concludes that they have an aqueous origin, being formed from above downwards by the action of infiltrating rain-water, and that animal remains were the only source of phosphorus in the deposits.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE SPELLING OF GEOGRAPHIC NAMES.

AT the regular monthly meeting of the U. S. Board on Geographic Names, held a few days ago, decisions were made as to the spelling of 149 geographic names. This Board, it will be remembered, is composed of ten members, representing those bureaus and departments of the government which are more or less concerned with geographic publications. It was created by executive order September 4, 1890, to the end that uniform usage in regard to geographic nomenclature and orthography shall obtain

throughout the executive departments of the government and particularly upon its maps and charts.

Among the decisions rendered were a few of general interest. These relate to names brought into prominent notice through the Klondike gold excitement.

As to *Klondike*, the decision is to spell it as here given, and *not* Clondyke, Klondyke, Chandike, Chandik or Deer, Reindeer, Trondike, nor Thron Diuck.

One of the lakes of the upper Yukon was named *Lebarge* by the Western Union Telegraph Expedition in 1868, after Mike Lebarge, a member of the exploring party, and a popular member, it may be added, who is now living somewhere near Ottawa, Canada. Late publications have fallen into the error of writing this Labarge, but the Board adheres to the original form, Lebarge. There is a Lebarge River in Alaska.

When Schwatka discovered the Yukon, in 1883, he named one of the lakes on its headwaters *Lindeman*, after Dr. Moritz Lindeman, now Vice-President of the Bremen Geographical Society. This sometimes appears, erroneously, as Lindemann and Linderman. The Board adopts Lindeman.

One of the principal tributaries of the upper Yukon is the *Lewes* river, named by Mr. Robert Campbell, of the Hudson Bay Company, about 1848. This is often miscalled Lewis.

The inlet, river and village at the head of Lynn canal, which now appears in the newspapers, almost daily, under the form Dyea, is an Indian word, which has appeared in many forms. Admiral Meade, in 1869, wrote it Tyÿa; Krause, in 1882; wrote it Dejäh; Schwatka, in 1883, Dayay; Dall, in 1883, Taiya. The Board adopts the form *Taiya*.

For the lake and river variously called Hootalinqua, Hotalinga, Teslin-hina, Teslin-too or Teslin the Board adopts *Teslin*. The terminations 'hina' and 'too' are said to mean river in different Indian dialects.

An Indian village on the middle Yukon is called *Nuklukayet*. This has been written in several forms, including the erroneous one, Tuklukyet.

W. F. MORSELL.

THE 'KAISER WILHELM DER GROSSE.'

THE North German Lloyd steamer 'Kaiser Wilhelm der Grosse' arrived at the port of New York on the 26th of September, her maiden voyage proving extraordinarily satisfactory. This ship is in many respects very remarkable. She is the largest ship afloat and nearly as large as the now non-existent 'Great Eastern;' the speed on her voyage, for a single day's run, exceeded that of any ship ever set afloat, not excepting the Cunarders 'Campagnia' and the 'Lucania;' the record for the run between Southampton and New York was broken, and the speed of the ship was such that had the voyage been between Liverpool and New York the run would have been considerably shorter than that of any steamer on that route. Not the least remarkable fact is that this new record was made on her maiden voyage.

The ship has the following dimensions; beside which are here given those of the 'Great Eastern,' the marine wonder of forty years ago:

	K. W.	G. E.
Length over all	649	697
Length between perpendiculars	625	680
Beam	66	83
Draught	26	30
Depth	43	58
Gross tonnage	14,000	19,500
Displacement	20,000	27,000
Horse-power	30,000	12,000
Speed, knots	23	12

The 'City of Rome,' of the last decade, is 561 feet long; the 'Campagnia' and the 'Lucania,' now two years old, are 625 feet long; and the length of the 'Oceanic,' of the White Star Line, now under construction, is 704 feet. The 'Kaiser' is very steady, having been fitted with bilge-keels to prevent rolling in a seaway.

The driving engines of the 'Kaiser' are 'triple-expansion,' one engine on each of her twin-screw shafts, with steam-cylinders 52, 89¾ and 96½ inches (two of the latter to each engine) diameter, and drive two three-bladed screws, 22 feet 3¾ inches diameter, 32 feet and 10 inches pitch, with a maximum of 30,000 horse-power, at the rate of twenty-three knots through the water (twenty-six miles an hour).

The propeller shafts weigh 166 tons, the bronze screws 26 tons each. The condensers contain 35,522 square feet of cooling surface, their 11,000 tubes measuring a total length of about thirty-five miles. There are, altogether, 68 engines on the ship, with 124 steam-cylinders. The centrifugal pumps and the engine bilge-pumps can, together, expel 3,600 tons an hour. Four dynamos are employed for lighting purposes, supplying current to 1,600 25-candle-power lamps. The cost of this floating palace was $3,500,000.

The hull is very graceful and most imposing, with its lofty sides and extreme length, its four smoke-stacks and its several stories of deck-houses. It is enormously strong and is divided by 16 transverse bulkheads and one running longitudinally. The 14 boilers are in four groups, each in a separate compartment, and the two main engines are similarly isolated. A double bottom gives additional safety. Accommodations are provided for 350 first-cabin, and as many second-cabin and 800 steerage passengers, and for a crew of 450 men, including 17 engineers, 18 boilers, 90 stokers and 75 coal-passers. Room is found for bunkers capable of containing 4,950 tons of coal.

With steam at 180 pounds pressure this ship developed 28,430 horse-power and made a run of 564 knots in a single day—the highest record yet known. The run from Southampton to New York was made in 5 days, 22 hours, 35 minutes (3,050 nautical miles); averaging 22¾ knots for the fastest 24 hours, 21.39 for the voyage. About 500 tons of coal a day were burned on the trip. The record from Liverpool to New York, now held by the 'Lucania,' is 5 days, 7 hours and 23 minutes; but the 'Kaiser' could make the run in about 5 days—possibly in 4 days, 22 hours.

R. H. T.

THE AMERICAN JOURNAL OF PHYSIOLOGY.

THE number of investigations in physiology and its allied sciences now made in this country has grown so large that the present means of publication are no longer sufficient. Physiologists can no longer print in foreign countries, often in foreign languages, or in general medical journals, without stunting a growth which, unchecked, will come to be a gratification to every American and a wholesome influence in American medicine. To meet the needs of investigators in physiology, physiological chemistry, physiological pharmacology, bio-chemistry and certain other branches of biology, a special journal will be published, the first number appearing in January, 1898. *The American Journal of Physiology*, as the new publication will be called, will contain in each volume about five hundred pages, divided into parts or numbers, to be issued whenever material is received. It is expected that not more than one volume a year will be printed. The *Journal* will be edited by H. P. Bowditch, M.D., Boston; R. H. Chittenden, M.D., New Haven; W. H. Howell, M.D., Baltimore; F. S. Lee, M.D., New York; Jacques Loeb, M.D., Chicago; W. P. Lombard, M.D., Ann Arbor, and W. T. Porter, M.D., Boston.

It is not to be supposed that a journal devoted solely to the publication of original researches in physiology will ever do more than pay for its paper and printing, and it is probable that some years must pass before the new enterprise will cease to be a financial burden on a small number of investigators. Yet the need of such a publication is undoubted. The aid of all friends of learning is asked until the *Journal* shall be established on a self-supporting basis. The subscription price, which is five dollars per volume, should be sent to W. T. Porter, M.D., 688 Boylston Street, Boston, Mass.

GENERAL.

THE American Chemical Society will hold its annual winter meeting at Washington on December 29th and 30th.

AT the recent Brunswick meeting of the German Society of Men of Science and Physicians a resolution introduced by Professors Virchow, Waldeyer and Neumayer was adopted, asking the Emperor for a grant (from the Royal fund for various purposes) for a deep-sea expedition to the Indian Ocean.

THE Southern Mahratta Railway will give free passes to observers of the total eclipse of the sun on January 22, 1898.

DR. MITSUKURI, professor of zoology at the

Imperial University of Tokyo, and Shirofujita, Director of the Commercial Bureau of the Department of Agriculture, have been appointed commissioners from Japan to attend the conference on the seal fisheries to be held shortly at Washington. M. Pierre Botkin has been appointed commissioner from Russia. If the commission is composed of men of science of high rank the results of the conference will carry much weight, even though Great Britain and Canada decline to send representatives.

PROFESSORS J. J. STEVENSON, J. F. KEMP and R. E. DODGE gave an informal reception to Professor Albrecht Penck, of Austria, at the Teachers' College, New York City, on October 7th. Owing to the short time allowed for arrangements, but a small party were present, composed largely of the geologists and geographers of the vicinity of New York. The Committee were also very fortunate in being able to greet Sir John Evans, who was in the city for but a few days. The New York Academy of Sciences had planned to give a reception to Sir John Evans and Lord Kelvin, but a time could not be arranged.

DR. FRIDTJOF NANSEN will read a paper on some of the scientific aspects of his recent Arctic exploration before the American Philosophical Society on Friday afternoon, October 29th.

DR. NEWTON C. BATES has been appointed Surgeon-General and Chief of the Bureau of Medicine and Surgery of the Navy, to succeed Surgeon-General Tryon.

PROFESSOR VLADIMIR I. BELAJEFF, professor of botany in the University of Warsaw, has been appointed Director of the Botanical Garden in that city, and Professor Vladimir I. Palladin, of Kharkoff, has been made Director of the Pomological Garden at Warsaw.

THE College of Physicians of Philadelphia has awarded its Alvarenga prize for 1897 to Dr. Joseph Collins, of New York, for a paper on 'Aphasia.'

WE learn from *Natural Science* that the first Flükiger medal—an honor to be awarded every five years by the German and Swiss Pharmaceutical Societies alternately—has been presented to Mr. Edward Morrell Holmes, Curator of the Museum of the Pharmaceutical Society of Great Britain. An account of Mr. Holmes' work in botany, illustrated by a portrait, appears in the *Pharmaceutical Journal* for September 4th.

THE Zoological Society, London, has conferred its silver medal on Mr. Alexander White, for his studies on the fauna of Nyassaland.

MR. G. H. DARWIN, professor of astronomy at Cambridge, now on his way to America to give a course of ten lectures on 'Tides' at the Lowell Institute, has been elected a foreign member of the Academia dei Lincei, Rome.

MESSRS. ROBERT G. AITKEN and W. H. WRIGHT have been appointed assistant astronomers at the Lick Observatory.

PROFESSOR F. W. CLARKE, Chief Chemist of the Geological Survey, has been appointed, by the Secretary of the Interior, Representative of the Department of the Interior and its several bureaus at the Omaha Exposition. Professor Clarke, who now represents the Department at the Nashville Exposition, has held a similar position in connection with every previous exposition in which the general government has taken part in recent years.

DR. WESLEY MILLS, professor of physiology in McGill University, has been given leave of absence for a year, which he will spend abroad. Correspondence, however, addressed to McGill University will be forwarded to him.

A STATUE of Balboa, the discoverer of the Pacific Ocean, will be erected in Golden Gate Park, San Francisco. It will be executed by Mr. Douglas Tilden, and is the gift of Mayor Phelan.

WE regret to record the deaths of Professor Charles T. Roy, since 1884 professor of pathology in Cambridge University, aged forty-seven years; of Mr. W. A. Stiles, Park Commissioner of New York City and editor of *Garden and Forest*, in Jersey City on October 6th, at the age of sixty years; of Dr. Herman Welcker, formerly professor of anatomy at the University at Halle, at Winterstein at the age of seventy-five years, and of Dr. Konrad Bohn, professor of mathematics and physics at the Forestry Institute at Aschaffenburg.

A DISPATCH from Melbourne states that the expedition of the Sydney Geographical Society, under Professor David, to the Ellice Islands, between the Gilbert Islands and the Fiji Islands, has obtained evidence confirming the theory of Darwin as to the formation of coral islands. Diamond drilling in coral to the depth of 557 feet failed to reach bottom.

A SOCIETY entitled 'Société des Sylviculteurs de France et des Colonies' is being formed in France, as has been learned from *Garden and Forest*, for the purpose of diffusing the knowledge of silviculture and increasing popular interest in this art.

DURING the year ending June 15, 1897, there have been added to the library of the University of Chicago 10,717 books, of which 7,383 were purchased, 2,930 were added by gift and 404 in exchange for University publications.

THE preliminary plans of the New York Zoological Park, to be located in South Bronx Park, New York, have been completed and will be submitted first to the President and the Executive Committee, then to a committee of three experts, consisting of Professor Charles S. Sargent, director of the Arnold Arboretum; Thomas Hastings, architect, and W. Barclay Parsons, civil engineer. If their reports are favorable the plans will then be submitted without delay to the Board of Park Commissioners. With the final plan of the Zoological Park grounds will be submitted the plans and elevations for the following buildings: The lion house, the monkey house, the elephant house, bird house, winter house for birds, reptile house, tropical ruminants' house, main restaurant and administration building. Of secondary structures will be submitted the plans for the flying cage, eagles' and vultures' aviary, wolf and fox dens, bear dens, sea lions' pool, pheasants' aviary, buffalo house, deer barns, mountain sheep shelter and ducks' aviaries. If the society's plans are approved by the experts and the Park Commissioners, the engineers will prepare plans for a system of sewerage and water supply.

THE London correspondent of the New York *Evening Post* telegraphs that at Maidstone vaccination is being used against typhoid under the direction of the pathological laboratory of the State Army School at Netley. Professor Wright and Surgeon-Major Temple, of Netley, have so improved the method that they are able to obtain the characteristic reaction of blood serum on typhoid bacilli, which is taken as a proof that the individual is protected by the injection. Enough vaccine has been sent to Maidstone to inoculate the whole population if necessary. The number of cases of typhoid fever reported is greater than 1,500.

ADVICES from Honolulu state that the lava in the crater of Kilauea has risen over 100 feet in eight days and that an overflow is expected.

THE report of the trustees of the South African Museum, Cape Town, for 1896, says *Natural Science*, records the reorganization of the staff and the completion of the new buildings. The Museum now has the services of Mr. W. L. Sclater as Director; Mr. L. Peringuey as Assistant Director, with special charge of the insects; Dr. W. F. Purcell as keeper of land invertebrates; Dr. G. S. Corstorphine as keeper of geology and mineralogy, and Dr. J. D. F. Gilchrist as honorary keeper of marine invertebrates. During the year 1896 a special grant was expended upon the purchase of a series of large mammals for the collection, while an exchange with the La Plata Museum furnished an important series of South American mammals and birds. Large acquisitions of European rocks and fossils were also purchased for comparison with the South African specimens.

THE Honorable William T. Harris, United States Commissioner of Education, will deliver five lectures on 'The Philosophy of Education' at the Teachers' College, New York, on the following dates: Thursdays, October 14th and 28th and November 4th, at 3:30 p. m.; Fridays, October 15th, at 2 p. m., and October 29th, at 3 p. m.

A COURSE of twelve lectures on the 'The Geological History of Invertebrate Animals' is being delivered by R. H. Traquair, M.D., F.R.S., in the Lecture Theatre of the South Kensington Museum. These are the Swiney Lectures on Geology, given under the direction of the trustees of the British Museum.

THE American Forestry Association has held a special meeting at Nashville, Tenn., with an excursion to Biltmore and Chattanooga, leaving Washington for Biltmore on the night of of September 16th. The party were entertained at Biltmore by Dr. Schenck, who explained and illustrated the methods of forestry management used on the estate of 1,300 acres. The chief meeting was held at Nashville on September 22d, at which papers were presented by Messrs. George B. Sudworth, J. B. Killegrew and others.

THE Macmillan Company will have ready for publication in the autumn the first volume of 'The Scientific Papers of Henry T. Huxley,' reprinted from the journals of scientific societies, edited by Professor Michael Foster and Professor E. Ray Lankester. The scientific papers are expected to fill four volumes.

THE current number of *Nature* (September 30) publishes the address on 'Long Range Temperature and Pressure Variables in Physics' given by Professor Barus as Vice-President, before the Section of Physics at the Detroit meeting of the American Association.

PROFESSOR J. J. THOMPSON'S work on the 'Elements of the Mathematical Theory of Electricity and Magnetism' has been translated into German by Professor Gustav Wertheim, being published by Friedrich Vieweg, Brunswick.

UNIVERSITY AND EDUCATIONAL NEWS.

AT a meeting of the trustees of Columbia University, on October 4th, President Low presented the following letter:

COLUMBIA UNIVERSITY IN THE CITY OF NEW YORK.
PRESIDENT'S ROOM.

October 4, 1897.

To the Trustees: As I have felt constrained by a sense of public duty to accept a nomination for Mayor of the City of New York at the hands of the Citizens' Union, I feel it to be my duty to the University to place in your hands for such action as you may see fit to take my resignation as President of the University.

I need not say that nothing but a deep sense of the imperative nature of the call to public duty would have led me to accept the nomination.

Respectfully,
SETH LOW.

The letter of resignation was referred to a committee, which cannot report until the next meeting of the trustees, on November 15th, when the election will have taken place.

THE 22d of October will hereafter be celebrated at Princeton University as Charter Day. Ex-President Cleveland will this year make the address. A short address is also expected from the Earl of Aberdeen, Governor-General of Canada, on whom a degree will be conferred.

PRESIDENT HARPER, of the University of Chicago, reports in his quarterly statement that there were in the University 169 instructors, of whom 19 are head professors, 22 professors, 27 associate professors and 21 assistant professors. The average salary for the year 1896-7 for all departments, including University Extension Division and the Divinity School, was $2,108.52.

THE Union of the Medical Departments of New York University and of Bellevue Hospital Medical College having failed, the building of the latter institution, which was destroyed by fire, has been rebuilt, and the College was opened on September 28th. Professor Lusk, whose death we were recently compelled to record, has been succeeded as president by Dr. Edward B. Janeway and as clinical professor of gynæcology by Dr. Henry C. Coe. Dr. Henry H. Rusby has been appointed professor of materia medica and pharmacology, and Dr. John A. Mandel, professor of chemistry.

ACCORDING to a letter to the Boston *Transcript* the serious damage suffered by Johns Hopkins University through the lapsing of dividends on Baltimore & Ohio stock has aroused the Baltimore Board of Trade to consider the question of extending aid to the institution from the public treasury. The Board will probably memorialize the State Legislature at its approaching session, setting forth the great advantage to Baltimore in a hundred different ways of having the University, and drawing attention to the probability that the very block of stock which has brought such loss to the University had been previously owned by the State, so that the University is only bearing a burden which the State itself might otherwise have borne.

Mr. W. W. Allis, of Milwaukee, has given Columbia University the equipment for a steam engineering laboratory containing a number of valuable pieces of machinery valued at more than $15,000.

Miss Olivia Phelps Stokes has given Barnard College $5,000, the income of which is to be used for aiding poor students.

Mr. A. J. Balfour has informed the authorities of Cambridge University that a friend of his who desired to remain anonymous wished to give £2,000 for general university purposes, in four installments, the first of which has been paid.

DISCUSSION AND CORRESPONDENCE.

THE EASTERNMOST VOLCANOES OF THE UNITED STATES.

To the Editor of Science: In looking through Professor I. C. Russell's magnificent volume on the 'Volcanoes of North America,' I was surprised to see (page 129) the statements that 'No volcanoes sufficiently recent to be recognized by their topographic forms occur east of the sharply defined eastern border of the Cordilleran mountain series,' and on page 191 he also says that the volcanoes occur in the Cordilleran region west of the meridian of Denver. On Plate 5 a map is given showing the distribution of volcanoes in the United States, upon which none are given east of the Rio Grande except the Spanish Peaks.

These conclusions on the part of Professor Russell are erroneous and mar his otherwise excellent work, for some of the most beautiful and perfect volcanic craters in the United States occur in New Mexico, not only far east of the longitude of Denver, but fully 200 miles east of the true Rocky Mountain front, which extends between Trinidad and Las Vegas.* These, as

have been described by the writer,† consist of a group of craters lying to the south of Folsom Station, in an eroded plain at the foot of the older lava capped Trinidad Mesa, which extends eastward from the Rocky Mountains for

*A brief notice of Mount Capulin was published by Orestes St. John in 'Notes on the Geology of Northwestern New Mexico;' Bull. U. S. Geol. and Geog. Survey of the Territories, Vol. II., 1876.

†Bull. Geol. Soc. Am., Vol. 3, p. 99, 1891.

a hundred miles or more along the Colorado-New Mexican line. The most conspicuous of these craters is Mount Capulin, six miles south of Folsom Station. This, a beautiful cinder cone (altitude 9,000 feet), rises nearly 2,750 feet above the railroad, with a vast crater at its top nearly a mile in diameter, slightly broken down on its western side. From its summit many flows can be traced. To the southward, from six to twenty miles, there are several similar craters, while to the northward there are several smaller ones. Around these craters there are numerous surface flows of vesicular, ropy lava, extending eastward to within sight of the Texas line.

These are the easternmost known craters of the Rocky Mountain region, and their occurrence at the foot of the Raton plateau, near the western edge of the Llano Estacado, is interesting. The cinder cones are clearly of a more recent origin than the adjacent basaltic cap of the Raton plateau, for they are situated in an eroded valley between the main mesa and an outlier—the Sierra Grande—and at a lower altitude than either of them. They are also apparently more recent than the late Tertiary deposits of the Llano Estacado, the original surface of the lava resting upon the latter and not covered by it except in case of the wind-blown débris.

While these are the only craters of the United States which are east of the true Rocky Mountain front, there are other important ones lying east of the Rio Grande which have escaped Mr. Russell's notice, notably the Cerrito lying between Galisteo and the Rio Grande, consisting of several cones rising to nearly 1,000 feet above the plateau. Still to the southward in the great bolson desert, which lies between the Organ and Sacramento ranges of southern New Mexico, there is a comparatively recent volcanic cone from which a stream of mobile lava has flowed for sixty miles to the southward. There are also several other craters just west of the Rio Grande and El Paso, in southern New Mexico, which have escaped Professor Russell's notice.

The Folsom craters, east of the true Rocky Mountain front, are the ones which upset deductions which would otherwise be tenable concerning the occurrence of volcanic cones approximately along oceanic shore lines. A bulletin for the United States Geological Survey is being prepared upon the Folsom locality by Mr. S. Prentiss Baldwin, of Cleveland, Ohio, who, at my request, some years ago undertook a thorough exploration of that most interesting region.

In addition to the true cinder cone craters we have have specified, that portion of New Mexico east of the Coloradoan group of the Rocky Mountains (Snow Range) which ends abruptly near the latitude of Sante Fé, is unusually rich in older volcanic phenomena, such as superficial lava flows and old volcanic necks or stocks of the type of Mount Taylor or the Spanish Peak which Russell includes in his map as volcanoes and two of which, near Fort Union, he describes.

Besides the omission of the true craters of New Mexico, the work gives no reference to the old volcanic phenomena of the Texas region, such as occur so abundantly in the Trans-Pecos region, and to the eastward along the interior margin of the Coastal Plain, between Austin and Del Rio.

It would have made matters much clearer to the reader had Professor Russell used a series of symbols upon his map to distinguish the kinds of volcanoes there plotted, such as living craters, extinct craters and volcanic stocks representing the ruins of old craters.

The accompanying sketch of the Texas-New Mexican region giving supplementary data concerning the distribution of volcanic phenomena will be of value to the reader of the work. The black discs are true volcanic craters; the square stocks or necks of former craters, and the crosses, are laccolites.

Robert T. Hill.

LITERARY EMBRYOLOGY.

To the Editor of Science: In the *Atlantic* for this month is an article by Mr. Frederic Burk on the 'Training of Teachers.' On p. 553–554 occurs the following paragraph, in which I have ventured to italicize those parts which seem to me absolutely incorrect. It appears singular that in an article on *teaching*, severely criticising prevalent methods, there

should occur a very striking example of inaccurate *learning:*

"Embryology throws some suggestive light upon the radical difference of childhood from maturity. The human fœtus roughly follows the disjointed line of development which marks the evolution of animal life. *Up to four months before birth the organism is essentially an aquatic animal, provided with rudimentary gill slits and the developed nerves of equilibration characteristic of aquatic life. At a later stage it has a coat of hair, and a tail longer than its legs, with the necessary muscles for moving this organ. This class of singular phenomena constantly appear during the embryological period; they are nourished and growing rapidly for a time, as if the whole destiny of the organism were to become some one of the lower forms of animal life.* Then the purpose is more or less suddenly changed. New forms and new organs appear, displacing or absorbing the old, and the organism seems to obtain a new destiny, which in turn may wholly or partly disappear. Some of these forms do not wholly disappear, *and physiologists now enumerate in the adult human organism more than one hundred parts of the body which have no known function,* and whose presence cannot be explained except upon the theory that they are remnants, or rudimentary organs, of some of these broken tendencies through which the organism has passed. Such is the pineal gland, which was declared by Descartes to be the seat of the soul, but is now recognized as the remnant of the organ of vision as still found in lower reptiles. The semi-lunar fold at the internal angle of the eye *is the remnant of the third eyelid of marsupials.* The vermiform appendage, which is such a menace to human life, is the remnant of an enormous organ in herbivora. The ear muscles, which in few people are functional, are recognized as rudiments of muscles of much use to lower animals. In the earlier stages of the human fœtus the brain is made up of three parts, of which the hinder part is by far the longest, as in the case of lower animals. *There is then no trace of the cerebral hemispheres* which constitute so large a part of the adult brain, *just as there is no trace in the lower orders. The mid-brain later shows the same enlargement for the centers of sight and hearing that these portions have in birds and certain fishes.* Still later the proportions are reversed: *the hind-brain dwindles away relatively, to become the slight enlargement of the spinal cord at the base of the brain known as the medulla oblongata; the mid-brain shrivels, to become the small nodules known as the quadrigemina; and the narrow neck connecting the fore-brain and the mid-brain swells, to become the huge cerebral hemispheres. Embryological growth is clearly not a harmonious development. The line of growth is broken, proceeding in one direction for a time, and then suddenly turning off in a new direction, as if the organism were continually making mistakes and correcting them before it is too late.* The path of growth is strewn with the remnants of these abandoned tendencies."

Charles S. Minot.

THE 'ENCHANTED MESA.'

To the Editor of Science: As little as he needs it, so little would I object that what trifling credit may be involved should go to my great teacher and dearest friend. Quite unthinkingly, however, I have mentioned the fact, in type, that I first published the Quéres tradition of the 'Enchanted Mesa;' and as Science (September 17) refers to the legend as discovered by Bandelier and 'subsequently obtained' by me, the pupil seems to be left in the position of trying to rob his master.

Bandelier's *Final Report*, Part II., p. 313, seems sufficiently conclusive, and accords with his fixed habit of giving credit, even to humble sources.

I first published a skeleton of the legend in 1885. It was years later before I could round out the last detail of the folk-story—when I had become genuinely a friend (by their count and my own) with nearly all the old *principales* of Acoma. One of them, a noble and wise old man, already tottering in his nineties, rode sixty miles horseback to pass three days with me in my own pueblo, in the month of his death. Both of us felt that it was good-bye; for I was already packing for the long South American journey with Bandelier, and the old man knew his own time was short. We talked of many things of the years that had drawn us together, and of Acoma, our common love; and

again he told me in full the folk-tale of the Mesa Encantada. No student of ethnology or of men, looking at that fine old face, listening to that voice, could ever have been so flippant as to suggest that he was telling 'a tall story.' He was repeating, word for word, the scriptures (we would say for a parallel) as he had learned them at his father's knee, and as they had been 'told down' from father to son through centuries. These folk-stories are not told to careless strangers, nor to careful ones either. How difficult it is to get them in full has been amply recorded by Bandelier and Cushing, and is fully understood by all who have genuinely gathered Indian folk-lore.

The matter of precedence is not vital, but since Mr. Hodge's workmanlike achievement the final 'round-up' of the rock of Katzimo seems to be on, and it is well to have all the mavericks duly marked. The Indian tradition is vindicated, and under circumstances that, in any less rigorous court than that of science, would be deemed dramatic.

LOS ANGELES, CAL.

SCIENTIFIC LITERATURE.

Philosophy of Knowledge. An Inquiry into the Nature, Limits and Validity of Human Cognitive Faculty. By GEORGE TRUMBULL LADD, Professor of Philosophy in Yale University. New York, Charles Scribner's Sons. 1897. Pp. xv+614.

Professor Ladd's most widely known work has hitherto been done in the field of psychology. His *Elements of Physiological Psychology*, published ten years ago, was the first systematic account in English of the methods and results of that science. Since that time there have appeared from the pen of the same author, *Outlines of Physiological Psychology; Psychology, Descriptive and Explanatory; Philosophy of Mind* (an essay on the metaphysics of psychology); besides a work entitled *Introduction to Philosophy.* It has all along been evident to readers of Professor Ladd's works that his main interest is n those ultimate problems of theology and philosophy which are concerned with man's nature and destiny, and which demand for their answer some theory of his relation to other beings and to the ground of all reality. The author's procedure, however, as well as numerous explicit statements scattered throughout his writings, make it clear that he has considered it necessary to approach the discussion of these problems after a thorough study of the concrete facts regarding the nature of the human mind and its relation to the bodily organism. Professor Ladd's psychological labors thus furnish the basis for his philosophy. Having laid the foundation, he now proposes to see what structure can be erected upon it; or, as he himself expresses it, to show what is 'implicate' in the fact of human experience. It is the main business of the present volume to discuss the problems of knowledge; ontological questions are, in the main, reserved for future treatment. Nevertheless, as is pointed out, it is not possible to separate entirely ontology and epistemology. "Something as to the nature of the really existent is interwoven inextricably with the conscious life of the cognitive subject" (p. 348). Even in the present work, then, as we shall see later, a theory of reality is foreshadowed.

Before examining any of the doctrines of the book, it seems necessary to say a word regarding its spirit and purpose. The author's interest appears throughout to be practical quite as much as theoretical. "I have striven constantly," he says, "to make epistemology vital, —a thing of moment, because indissolubly and most intimately connected with the ethical and religious life of the age" (p. ix.). And it seems to him of the utmost importance to refute what he considers false and dangerous theories of knowledge. "The agnostic or despairing attitude towards the problem of knowledge itself lies, both logically and in fact, at the base of all other agnosticism, and of manifold forms of despair" (p. 28). If this conviction has sometimes led the author to adopt the language of a moral teacher or preacher, rather than that of an investigator, it has doubtless rendered his presentation more vigorous and his book more interesting, from the standpoint of the general reader, than would otherwise have been the case. It is probable, too, that in the author's consciousness of a mission is to be found the explanation of the remarkable statements in the

preface that 'there are no modern works in English from which any help is to be derived in the treatment of epistemological problems,' and that the present volume 'asks and should receive the treatment due to a pioneer work' (p. viii.). It is perhaps psychologically inevitable that the reformer should regard himself as standing alone, that he should be unable to see that there are other knees which have not bowed unto Baal. It will no doubt be encouraging to Professor Ladd to learn that, in spite of his conviction that no help is to be found in Mr. Hobhouse's recent work since it deals with logic (*vide*, note p. viii.), he may discover there a theory of knowledge similar in many respects to his own. There are also several other modern books on logic which cannot fairly be accused of treating the nature of thought in a merely formal way, and in which the fundamental conceptions which Professor Ladd himself uses are very clearly laid down. And among psychological writers there are surely several—Ward, James, Stout, to mention but three names—from whom some assistance might be derived in a discussion of the nature of cognition. My own opinion is that philosophers at the present day have some ground for encouragement and congratulation, in the fact that substantial agreement has been reached on so many important points connected with this very subject. While gladly acknowledging the independence and value of Professor Ladd's treatment, I should still say that it has been largely made possible by the work which has appeared in English during the last twenty years.

The first chapter of the volume is occupied with a discussion of the nature of the problem, while the two following chapters contain an excellent, though somewhat summary, account of historical theories of cognition. "The fundamental problem of the philosophy of knowledge is an inquiry into the relations between certain states of consciousness and what we conceive of as 'the really existing'" (p. 10). "It accepts as its problem cognition including all its necessary implicates" (p. 17). Among these implicates is that of an extra-mental reality different from the knowing subject. "To know is to make an ontological leap, a spring from the charmed circle of pure subjectivity into the mystery of the real" (p. 22). If we ask, now, how it is possible to guarantee the validity of knowledge, we find that it is impossible to discover any outside standard by means of which it may be tested. "Critical analysis of the nature of experience, with a view to certify it, ends in the discovery of aspects, or factors, or implicates, of every exercise of cognitive faculty which are self-certifying" (p. 105).

A point upon which great emphasis is laid is the objective nature of cognition. "It is the very reverse of truth to say that knowledge is *merely* subjective; for till the stream of consciousness, the state or the activity of the knowing subject, has become also objective, cognition has not taken place" (p. 115). Judgment, in which the cognitive activity involved in thinking culminates, "is not genuine judgment without a trans-subjective reference, an implication of the actual connection of different 'momenta' in a really existing world" (p. 149). Professor Ladd also strongly insists that knowing is not an affair of any one set of faculties, but involves the whole mind. Feeling and willing are implied in every cognitive act, and belong to the very nature of knowledge. Two chapters (Chap. vi., Knowledge as Feeling and Willing; and Chap. xvii., Ethical and Æsthetical Momenta of Knowledge) are devoted to enforcing and illustrating this doctrine, which is so often forgotten by those who discuss the nature of knowledge. "In the formation and criticism of every alleged cognitive judgment, the entire mind of the subject, whose is the judgment, takes part" p. 502). "The different aspects or sides of human nature do not stand apart, as it were, from the ordinary working of cognitive faculty. * * * The rather must they all be considered as factors, or 'momenta' essentially present and effective in the integrating process that gives the object as a totality to the mind, and that shapes the actual synthesis in which the cognitive judgment consists" (p. 503).

The author finds, further, that the reality of both subject and object, and also that of a relation between the two, are 'implicated' in every act of self-conscious experience. But how shall

we conceive of this relation? In cognition an obvious distinction of subject and object is presupposed. But their complete incomparability is denied, and their actual unification in some form is affirmed (p. 206). This unification can take place 'only if the conception of one of the two—either of thing or of self—can be so extended in a valid way as to provide an explanation for the other, and for the relation of knowledge between the two' (p. 216). The concept of the Self, the author finds, is alone capable of such extension. It furnishes the key or interpretation to all that we know about things. That is, it is only when things are conceived as in some sort analogous to the Self that they can be known at all. Our knowledge of the Self is direct and intuitive and has the highest degree of certainty. Indeed, it is because we fail to attain the same perfection in knowing, when dealing with things, that we become dissatisfied with the limits, etc., of our knowledge (p. 252). The author's doctrine on the nature of our knowledge of the Self requires further elaboration to render it perfectly clear. He seems, however, to believe that we here get beyond the antithesis of subject and object, and are, in a sense, face to face with reality. He himself sums up his chapter on the knowledge of Things and of Self as follows: "While the knowledge of Self may attain an intuitive penetration to the heart of reality, the knowledge of things remains an analogical interpretation of their apparent behavior into terms of a real nature corresponding, in important characteristics, to our own" (p. 226).

This conception of the Self as the central point of knowledge determines, to a very important extent, the character of the discussions which follow. The meaning of Identity and Difference and of the principle of Sufficient Reason are found in the nature of the Self. And, similarly, the author's conclusions regarding the teleological character of knowledge, and the necessity of employing teleology to understand completely the nature of things, follows directly from the doctrine that knowing is an interpretation of things by the Self in the light of what it knows about its own nature. The author's discussion of Experience and the Transcendent (Chap. xi.) is extremely interesting. We cannot, he argues, know anything that is not somehow implicate in our experience. But every experience implies the existence of conditions which transcend it as mere fact. Hence to know is just to reach beyond the mere factual aspect of experience to its underlying conditions (pp. 325–35).

The theory of reality outlined in the present volume shows marked traces of the influence of Lotze. No meaning can be given to the concept of related things "unless things are conceived of as self-active beings, with their various modes of behavior interdependent and yet united under a framework, so to speak, of immanent ideas" (p. 360). In the same way, the relation between the individual and the ground of reality is conceived as a relation of minds or selves. "Human cognition is all to be understood as a species of intercourse between minds. In all man's knowledge the real being of the finite Self is in actual commerce with the absolute Self. The relation of an intercourse between Selves is the one fundamental and permanent conception under which may be truthfully included all the particular forms of relation of which we have experience in the development of the life of cognition" (p. 558).

Cornell University.

Elementary Geology. By Ralph S. Tarr, B. S., F. G. S. A., Professor of Dynamic Geology and Physical Geography at Cornell University. New York, The Macmillan Company. 1897. Price, $1.40.

Occasion for the publication of another elementary text-book on geology, in addition to the number of good works previously available, is found in the 'need of a geology in which more stress is placed upon the dynamic aspect of the subject than is commonly given.' It is the author's opinion that stratigraphic geology—that is, as the term is used in this work, the history of the earth's development—contains too much abstract fact for the average high school student, whereas structural and dynamic geology, which treat respectively of the materials composing the earth's mass and the forces affecting it, may be presented in simpler form. "Here the body of fact necessary for

elementary understanding is not so great nor so difficult to grasp. The teachings of these truths of geology are illustrated on every hand, and in fact some of them are already familiar to the pupil before he enters upon the study. They deal with phenomena in the midst of which we dwell, and hence should become a part of the mental possessions of every high school pupil." The second reason for putting forth the book is to furnish a companion and adjunct to the 'Elementary Physical Geography,' by the same author.

There is much to be said for the view that in teaching geology a beginning can best be made with the study of the materials of the earth and the forces which modify it. Such a method transforms the study by substituting observation of our environment for book learning of past conditions. As the tendency of modern geologic interpretation is to seek in the records of the past for the effects of causes now operative, such a method is scientifically sound. Those who have found the author's work on 'Physical Geography' helpful will, no doubt, discover in this 'Elementary Geology' an aid to further studies.

To prepare an adequate elementary textbook is a task involving the successful reduction of three difficulties: the selection of material; the analysis of the subject-matter chosen, and the choice of language.

In the selection of material from the enormous mass of available facts the author determines the essential character of the book. This is his peculiar privilege, and detailed comment would only serve to illustrate another point of view. The choice for this volume is controlled by the emphasis given to the dynamic phase of the subject, and by the appropriate preference for American instances of world-wide phenomena.

With reference to the analysis of the subjects chosen and the precision of expression, more definite standards have been set by the masters of scientific exposition. Their example might well check too fluent thought and too facile pen. The present work is weak in analysis and statement. The writing is in a descriptive style, which is pleasant to read, but which lacks emphasis of leading ideas. Examples chosen to illustrate processes appear to have controlled the order of presentation rather than to have been controlled by a logical train of thought.

About one-hundred and fifty pages of the four hundred and eighty-seven are given to illustrations. The illustrations are, as a rule, well chosen, judging by those whose originals are familiar, but in reduction to a scale adequate for this work they have suffered very materially, and their value is in many instances doubtful Half-tone reductions printed as text figures rarely retain sufficient character to justify their use in works of this kind. The photograph should either be redrawn as line work or it should be printed upon a separate plate in a proper press. Either of these alternatives would limit the number of illustrations available for a book of moderate cost, but it would be better to have a few good ones than many which fail of their purpose.

The responsibility which rests upon the scientific author in attempting to promote the study of his subject can scarcely be too seriously considered. It is only in recognition of this responsibility that this review has been prepared.

ADDRESS OF THE PRESIDENT TO THE PHYSIOLOGICAL SECTION OF THE BRITISH ASSOCIATION.

WE who have come from the little island on the other side of the great waters to take part in this important gathering of the British Association have of late been much exercised in retrospection. We have been looking back on the sixty years' reign of our beloved Sovereign, and dwelling on what has happened during her gracious rule. We have, perhaps, done little in calling to mind the wrongs, the mistakes and the failures of the Victorian era; but our minds and our mouths have been full of its achievements and its progress; and each of us, of himself or through another, has been busy in bringing back to the present the events of more than half a century of the past. It was while I, with others, was in this retrospective mood that the duty of preparing some few words to say to you to-day seemed suddenly to change from an impalpable cloud in the far distance to a heavy burden pressing directly on the back; and in choosing something to say I have succumbed to the dominant influence. Before putting pen to paper, however, I recovered sufficiently to resist the temptation to add one more to the many reviews which have appeared of the progress of physiology during the Victorian era. I also rejected the idea of doing that for which I find precedents in past presidential addresses—namely, of at-

tempting to tell what has been the history of the science to which a Section is devoted during the brief interval which has elapsed since the Section last met; to try and catch physiology, or any other science, as it rushes through the brief period of some twelve months seemed to me not unlike photographing the flying bullet without adequate apparatus; the result could only be either a blurred or a delusive image. But I bethought me that this is not the first, we hope it will not be the last, time that the British Association has met in the Western Hemisphere; and though the events of the thirteen years which have slipped by since the meeting at Montreal in 1884 might seem to furnish a very slender oat on which to pipe a presidential address, I have hoped that I might be led to sound upon it some few notes which might be listened to.

And indeed, though perhaps when we come to look into it closely almost every period would seem to have a value of its own, the past thirteen years do, in a certain sense, mark a break between the physiology of the past and that of the future. When the Association met at Montreal in 1884, Darwin, whose pregnant ideas have swayed physiology in the limited sense of that word, as well as that broader study of living beings which we sometimes call biology, as indeed they have every branch of natural knowledge, had been taken from us only some two years before, and there were still alive most of the men who did the great works of physiology of the middle and latter half of this century. The gifted Claude Bernard had passed away some years before, but his peers might have been present at Montreal. Bowman, whose classic works on muscle and kidney stand out as peaks in the physiological landscape of the past, models of researches finished and complete so far as the opportunities of the time would allow, fruitful beginnings and admirable guides for the labors of others. Brown-Sequard, who shares with Bernard the glory of having opened up the great modern path of the influence of the nervous system on vascular and thus on nutritional events, and who, if he made some mistakes, did many things which will last for all time. Brücke, whose clear judgment, as shown in his digestive and other work, gave permanent value to whatever he put forth. Du Bois-Reymond, who, if he labored in a narrow path, set a brilliant example of the way in which exact physical analysis may be applied to the phenomena of living beings, and in other ways had a powerful influence on the progress of physiology. Donders, whose mind seemed to have caught something of the better qualities of the physiological organ to which his professional life was devoted, and our knowledge of which he so largely extended, so sharply did he focus his mental eye on every physiological problem to which he turned—and these were many and varied. Helmholtz, whose great works on vision and hearing, to say nothing of his earlier distinctly physiological researches, make us feel that if physics gained much, physiology lost even more when the physiologist turned aside to more distinctly physical inquiries. Lastly, and not least, Ludwig, who by his own hands or through his pupils did so much to make physiology the exact science which it is to-day, but which it was not when he began his work. I say lastly, but I might add the name of one who, though barred by circumstances from contributing much directly to physiology by way of research, so used his powerful influence in many ways in aid of physiological interests as to have helped the science onward to no mean extent, at least among English-speaking people—I mean Huxley. All these might have met at Montreal. They have all left us now. Among the peers of the men I have mentioned whose chief labors were carried on in the forties, the fifties

and the sixties of the century, one prominent inquirer alone seems to be left, Albert von Kölliker, who in his old age is doing work of which even he in his youth might have been proud. The thirteen years which have swept the others away seem to mark a gulf between the physiological world of to-day and that of the time in which most of their work was done.

They are gone, but they have left behind their work and their names. May they of the future, as I believe we of the present are doing, take up their work and their example, doing work other than theirs but after their pattern, following in their steps.

In the thirteen years during which these have passed away physiology has not been idle. Indeed, the more we look into the period the more it seems to contain.

The study of physiology, as of other sciences, though it may be stimulated by difficulties (and physiology has the stimulus of a special form of opposition unknown to other sciences), expands under the sunshine of opportunity and aid. And it may be worth while to compare the opportunities for study of physiology in 1884 with those in 1897. At this meeting of the British Association I may fitly confine myself, I was going to say, to British matters; but I feel at this point, as others have felt, the want of a suitable nomenclature. We who are gathered here to-day have, with the exception of a few honored guests from the Eastern Hemisphere, one common bond, one common token of unity, and, so far as I know, one only; I am speaking now of outward tokens; down deeper in our nature there are, I trust, yet others. We all speak the English tongue. Some of us belong to what is called Great Britain and Ireland, others to that which is sometimes spoken of as Greater Britain. But there are others here who belong to neither; though English in tongue, they are in no sense British. To myself, to whom the being English in speech is a fact of far deeper moment than any political boundary, and who wish at the present moment to deal with the study of physiology among all those who speak the English tongue, there comes the great want of some word which will denote all such. I hope, indeed I think, that others feel the same want too. The term Anglo-Saxon is at once pedantic and incorrect, and yet there is none other; and, in the absence of such a better term, I shall be forgiven if I venture at times to use the seemingly narrow word English as really meaning something much broader than British in its very broadest sense.

Using English in this sense, I may, I think, venture to say that the thirteen years which separate 1884 from to-day have witnessed among English people a development of opportunities for physiological study such as no other like period has seen. It is not without significance that only a year or two previous to this period, in England proper, in little England, neither of the ancient Universities of Oxford and Cambridge, which, historically at least, represent the fullest academical aspirations of the nation, possessed a chair of physiology; the present professors, who are the first, were both appointed in 1883. Up to that time the science of physiology had not been deemed worthy, by either university, of a distinctive professorial mechanism. The act of these ancient institutions was only a manifestation of modern impulses, shared also by the metropolis and by the provinces at large. Whereas up to that time the posts for teaching physiology, by whatever name they were called, had been in most cases held by men whose intellectual loins were girded for other purposes than physiology, and who used the posts as stepping-stones for what they considered better things, since that time, as each post became vacant, it had almost invariably been filled by men wishing and pur-

posing at least to devote their whole energies to the science. Scotland, in many respects the forerunner of England in intellectual matters, had not so much need of change; but she, too, has moved in the same direction, as has also the sister island.

And if we turn to this Western Continent, we find in Canada and in the States the same notable enlargement of physiological opportunity, or even a still more notable one. If the English-speaking physiologist dots on the map each place on this Western Hemisphere which is an academic focus of his science, he may well be proud of the opportunities now afforded for the development of English physiology; and the greater part of this has come within the last thirteen years.

Professorial chairs or their analogues are, however, after all but a small part of the provision for the development of physiological science. The heart of physiology is the laboratory. It is this which sends the life-blood through the frame; and in respect to this, perhaps, more than to anything else, has the progress of the past thirteen years been striking. Doubtless, on both sides of the waters there were physiological laboratories, and good ones, in 1884; but how much have even these during that period been enlarged and improved, and how many new ones have been added? In how many places, even right up to about 1884, the professor or lecturer was fain to be content with mere lecture experiments and a simple course of histology, with perhaps a few chemical exercises for his students! Now each teacher, however modest his post, feels and says that the authorities under whom he works are bound to provide him with the means of leading his students along the only path by which the science can be truly entered upon, that by which each learner repeats for himself the fundamental observations on which the science is based.

But there is a still larger outcome from the professorial chair and the physiological laboratory than the training of the student; these are opportunities not for teaching only, but also for research. And perhaps in no respect has the development during the past thirteen years been so marked as in this. Never so clearly as during this period has it become recognized that each post for teaching is no less a post for learning, that among academic duties the making knowledge is as urgent as the distributing it, and that among professorial qualifications the gift of garnering in new truths is at least as needful as facility in the didactic exposition of old ones. Thirteen years has seen a great change in this matter, and the progress has been perhaps greater on this side of the water than on the other, so far as English-speaking people are concerned. We on the other side have witnessed with envy the establishment on this side of a university, physiology having in it an honored place, the keynote of which is the development of original research. It will, I venture to think, be considered a strong confirmation of my present theme that the Clark University at Worcester was founded only ten years ago.

And here, as an English-speaking person, may I be allowed to point out, not without pride, that these thirteen years of increased opportunity have been thirteen years of increased fruitfulness. In the history of our science, among the names of the great men who have made epochs, English names, from Harvey onwards, occupy no mean place; but the greatness of such great men is of no national birth; it comes as it lists, and is independent of time and of place. If we turn to the more everyday workers, whose continued labors more slowly build up the growing edifice and provide the needful nourishment for the greatness of which I have just spoken, we may, I will dare to say, affirm that the last thirteen

years has brought contributions to physiology, made known in the English tongue, which, whether we regard their quanity or their quality, significantly outdo the like contributions made in any foregoing period of the same length. Those contributions have been equally as numerous, equally as good on this side as on the other side of the waters. And here I trust I shall be pardoned if personal ties and affection lead me to throw in a personal word. May I not say that much which has been done on this side has been directly or indirectly the outcome of the energy and gifts of one whom I may fitly name on an occasion such as this, since, though he belonged to the other side, his physiological life was passed and his work was done on this side, one who has been taken from us since this Association last met, Henry Newell Martin?

Yes, during these thirteen years, if we put aside the loss of comrades, physiology has been prosperous with us and the outlook is bright; but, as every cloud has its silver lining, so shadow follows all sunshine, success brings danger, and something bitter rises up amid the sweet of prosperity. The development of which I have spoken is an outcome of the progressive activity of the age, and the dominant note of that activity is heard in the word 'commercial.' Noblemen and noblewomen open shop, and every one, low as well as high, presses forward towards large or quick profits. The very influences which have made devotion to scientific inquiry a possible means of livelihood, and so fostered scientific investigation, are creating a new danger. The path of the professor was in old times narrow and strait, and only the few who had a real call cared to tread it; nowadays there is some fear lest it becomes so broad and so easy as to tempt those who are in no way fitted for it. There is an increasing risk of men undertaking a research, not because a question is crying out to them to be answered, but in the hope that the publication of their results may win for them a lucrative post. There is, moreover, an even greater evil ahead. The man who lights on a new scientific method holds the key of a chamber in which much gold may be stored up; and strong is the temptation for him to keep the new knowledge to himself until he has filled his fill, while all the time his brother-inquirers are wandering about in the dark through lack of that which he possesses. Such a selfish withholding of new scientific truth is beginning to be not rare in some branches of knowledge. May it never come near us!

Now I will, with your permission, cease to sound the provincial note, and ask your attention for a few minutes while I attempt to dwell on what seem to me to be some of the salient features of the fruits of physiological activity, not among English-speaking people only, but among all folk, during the past thirteen years.

When we review the records of research and discovery over any lengthened period, we find that in every branch of the study progress is irregular, that it ebbs and flows. At one time a particular problem occupies much attention, the periodicals are full of memoirs about it, and many of the young bloods flash their maiden swords upon it. Then again for a while it seems to lie dormant and unheeded. But quite irrespective of this feature, which seems to belong to all lines of inquiry, we may recognize two kinds of progress. On the one hand, in such a period, in spite of the waves just mentioned, a steady advance continually goes on in researches which were begun and pushed forward in former periods, some of them being of very old date. On the other hand, new lines of investigation, starting with quite new ideas or rendered possible by the introduction of new methods, are or may be begun. Such nat-

urally attract great attention, and give a special character to the period.

In the past thirteen years we may recognize both these kinds of progress. Of the former kind I might take, as an example, the time-honored problems of the mechanics of the circulation. In spite of the labor which has been spent on these in times of old, something always remains to be done, and the last thirteen years have not been idle. The researches of Hürthle and Tigerstedt, of Roy and Adami, not to mention others, have left us wiser than we were before. So again, with the also old problems of muscular contraction, progress, if not exciting, has been real ; we are some steps measurably nearer understanding what is the exact nature of the fundamental changes which bring about contraction and what are the relations of those changes to the structure of muscular fibre. In respect to another old problem, too, the beat of the heart, we have continued to creep nearer and nearer to the full light. Problems again, the method of attacking which is of more recent origin, such as the nature of secretion, and the allied problem of the nature of transudation, have engaged attention and brought about that stirring of the waters of controversy which, whatever be its effects in other departments of life, is never in science wholly a waste of time, if indeed it be a waste of time at all, since, in matters of science, the tribunal to which the combatants of both sides appeal is always sure to give a true judgment in the end. In the controversy thus arisen, the last word has perhaps not yet been said, but whether we tend at present to side with Heidenhain, who has continued into the past thirteen years the brilliant labors which were, perhaps, the distinguishing features of physiological progress in preceding periods, and who in his present sufferings carries with him, I am sure, the sympathies, if not the hopes, of all his brethren, or whether we are more inclined to join those who hold different views, we may all agree in saying that we have, in 1897, distinctly clearer ideas of why secretion gathers in an alveolus or lymph in a lymph space than we had in 1884.

I might multiply such examples of progress on more or less old lines until I wearied you; but I will try not to do so. I wish rather to dwell for a few minutes on some of what seems to be the salient new features of the period under review.

One such feature is, I venture to think, the development of what may perhaps be called the new physiological chemistry. We always are, and for a long time have been, learning something new about the chemical phenomena of living beings. During the years preceding those immediately recent, great progress, for which we have especially, perhaps, to thank Kühne, was made in our knowledge of the bodies which we speak of as proteids and their allies. But while admitting to the full the high value of all these researches, and the great light which they threw on many of the obscurer problems of the chemical changes of the body, such, for instance, as the digestive changes and the clotting of blood, it could not but be felt that their range was restricted and their value limited. Granting the extreme usefulness of being able to distinguish bodies though their solution or precipitation by means of this or that salt or acid, this did not seem to promise to throw much light on the all-important problem as to what was the connection between the chemical constitution of such bodies and their work in the economy of a living being. For it need not be argued that this is an all-important problem. To-day, as yesterday and in the days before, the mention of the word vitalism or its equivalent separates as a war-cry physiologists into two camps, one contending that all the phenomena of life can, and

the other that they cannot, be explained as the result of the action of chemico-physical forces. For myself, I have always felt that while such a controversy, like other controversies as I ventured to say just now, is useful as a stirring of the waters, through which much oxygen is brought home to many things and no little purification effected, the time for the final judgment on the question will not come until we shall more clearly understand than we do at present what we mean by physical and chemical, and may, perhaps, be put off until somewhere near the end of all things, when we shall know as fully as we ever shall what the forces to which we give these names can do and what they cannot. Meanwhile, the great thing is to push forward, so far as may be, the chemical analysis of the phenomena presented by living beings. Hitherto the physiological chemists, or the chemical physiologists as perhaps they ought rather to be called, have perhaps gone too much their own gait, and have seemed to be constructing too much a kind of chemistry of their own. But that, may I say, has in part been so because they did not receive from their distinctly chemical brethren the help of which they were in need. May I go so far as to say that to us physiologists these our brethren seemed to be lagging somewhat behind, at least along those lines of their science which directly told on our inquiries? That is, however, no longer the case. They are producing work and giving us ideas which we can carry straight into physiological problems. The remarkable work of Emil Fischer on sugars, one of the bright results of my period of thirteen years, may fully be regarded as opening up a new era in the physiology of the carbohydrates; opening up a new era because it has shown us the way how to invesigate physiological problems on purely and distinctively chemical lines. Not in the carbohydrates only, but in all directions our younger investigators are treating the old problems by the new chemical methods; the old physiological chemistry is passing away; nowhere, perhaps, is the outlook more promising than in this direction; and we may at any time receive the news that the stubborn old fortress of the proteids has succumbed to the new attack.

Another marked feature of the period has been the increasing attention given to the study of the lower forms of life, using their simpler structures and more diffuse phenomena to elucidate the more general properties of living matter. During the greater part of the present century physiologists have, as a rule, chosen as subjects of their observations almost exclusively the vertebrata; by far the larger part of the results obtained during this time have been gained by inquiries restricted to some half a dozen kinds of backboned animals; the frog and the myograph, the dog and the kymograph, have almost seemed the alpha and the omega of the science. This has been made a reproach by some, but, I cannot help thinking, unjustly. Physiology is, in its broad meaning, the unravelling of the potentialities of things in the conditions which we call living. In the higher animals the evolution by differentiation has brought these potentialities, so to speak, near the surface, or even laid them bare as actual properties capable of being grasped. In the lower animals they still lie deep buried in primeval sameness; and we may grope among them in vain unless we have a clue furnished by the study of the higher animal. This truth seems to have been early recognized during the progress of the science. In the old time, observers such as Spallanzani, with but a moderate amount of accumulated knowledge behind them, and a host of problems before them, with but few lines of inquiry as yet definitely laid down, were free to choose the subjects of their investigation where they pleased, and in the

wide field open to them prodded, so to speak, among all living things, indifferent whether they possessed a backbone or no. But it soon became obvious that the study of the special problems of the more highly organized creature was more fruitful, or at least more easily fruitful, than that of the general problems of the simpler forms; and hence it came about that inquiry, as it went on, grew more and more limited to the former. But an increasing knowledge of the laws of life as exemplified in the differentiated phenomena of the mammal is increasingly fitting us for a successful attack on the more general phenomena of the lowly creatures possessing little more than that molecular organization, if such a phrase be permitted, which alone supplies the conditions for the manifestation of vital activities. And, though it may be true that in all periods men have from time to time labored at this theme, I think that I am not wrong in saying that the last dozen years or so mark a distinct departure both as regards the number of researches directed to it, and also, what is of greater moment, as regards the definiteness and clearness of the results thereby obtained. One has only to look at the results recorded in the valuable treatises of Verworn and Biedermann, whether obtained by the authors themselves or by others, to feel great hope that in the immediately near future a notable advance will be made in our grasp of the nature of that varying collection of molecular conditions, potencies and changes, slimy hitherto to the intellectual no less than to the physical touch, which we are in the habit of denoting by the more or less magical word protoplasm. And, perhaps, one happy feature of such an advance will be one step in the way of that reintegration which men of science fondly hope may ultimately follow the differentiation of studies now so fierce and attended by many ills; in the problems of protoplasm the animal physiologist touches hands with the botanist, and both find that under different names they are striving towards the same end.

Closely allied to and, indeed, a part of the above line of inquiry is the study of the physiological attributes of the cell and of their connection with its intrinsic organization. This is a study which, during the last dozen years, has borne no mean fruits; but it is an old study, one which has been worked at from time to time, reviving again and again as new methods offered new opportunities. Moreover, it will probably come directly before us in our sectional work, and, therefore, I will say nothing more of it here.

Still another striking feature of the past dozen years has been the advance of our knowledge in regard to those events of the animal body which we have now learned to speak of as 'internal secretion.' This knowledge did not begin in this period. The first note was sounded long ago in the middle of the century, when Claude Bernard made known what he called 'the glycogenic function of the liver.' Men, too, were busy with the thyroid body and the suprarenal capsules long before the meeting of the British Association at Montreal. But it was since then, namely in 1889, that Minkowski published his discovery of the diabetic phenomena resulting from the total removal of the pancreas. That, I venture to think, was of momentous value, not only as a valuable discovery in itself, but especially, perhaps, in confirming and fixing our ideas as to internal secretion, and in encouraging further research.

Minkowski's investigation possessed this notable feature, that it was clear, sharp and decided, and, moreover, the chief factor, namely sugar, was subject to quantitative methods. The results of removing the thyroid body had been to a large extent general, often vague, and in some cases uncertain; so much so as to justify, to a cer-

tain extent, the doubts held by some as to the validity of the conclusion that the symptoms witnessed were really and simply due to the absence of the organ removed. The observer who removes the pancreas has to deal with a tangible and measurable result, the appearance of sugar in the urine. About this there can be no mistake, no uncertainty. And the confidence thus engendered in the conclusion that the pancreas, besides secreting the pancreatic juice, effects some notable change in the blood passing through it, spread to the analogous conclusions concerning the thyroid and the suprarenal, and moreover suggested further experimental inquiry. By those inquiries all previous doubts have been removed; it is not now a question whether or no the thyroid carries on a so-called internal secretion; the problem is reduced to finding out what it exactly does and how exactly it does it. Moreover, no one can at the present day suppose that this feature of internal secretion is confined to the thyroid, the suprarenal and the pancreas; it needs no spirit of prophecy to foretell that the coming years will add to physiological science a large and long chapter, the first marked distinctive verses of which belong to the dozen years which have just passed away.

The above three lines of advance are of themselves enough to justify a certain pride on the part of the physiologist as to the share which his science is taking in the forward movements of the time. And yet I venture to think that each and all of these is wholly overshadowed by researches of another kind, through which knowledge has made, during the past dozen years or so, a bound so momentous and so far-reaching that all other results gathered in during the time seem to shrink into relative insignificance.

It was a little before my period, in the year 1879, that Golgi published his modest note, 'Un nuovo processo di technica microscopia.'* That was the breaking out from the rocks of a little stream which has since swollen into a great flood. It is quite true that long before a new era in our knowledge of the central nervous system had been opened up by the works of Ferrier and of Fritch and Hitzig. Between 1870 and 1880 progress in this branch of physiology had been continued and rapid. Yet that progress had left much to be desired. On the one hand, the experimental inquiries, even when they were carried out with the safeguard of an adequate psychical analysis of the phenomena which presented themselves, and this was not always the case, sounded a very uncertain note, at least when they dealt with other than simply motor effects. They were, moreover, not unfrequently in discord with clinical experience. In general the conclusions which were arrived at through them, save such as were based on the production of easily recognized and often measurable movements, were regarded by many as conclusions of the kind which could not be ignored, which demanded respectful attention, and yet which failed to carry conviction. It seemed to be risking too much to trust too implicitly to the apparent teaching of the results arrived at; something appeared wanting to give these their full validity, to explain their full and certain meaning by showing their connection with what was known in other ways and by other methods. On the other hand, during nearly all this time, in spite of the valuable results acquired by the continually improving histological technique, by the degeneration method and by the developmental method, by the study of the periods of myelination, most of us, at all events, were sitting down, as our forefathers had done, before the intricate maze of encephalic structure, fascinated by its complexity, but

*_Rendiconti del reale Istitulo Lombardo_, Vol. XII., p. 206.

wondering what it all meant. Even when we attempted to thread our way through the relatively simple tangle of the spinal cord, to expect that we should ever see our way so to unravel out the strands of fibres, here thick, there thin, now twisting and turning, and anon running straight, or so to set out in definite constellations the seeming milky way of star-like cells, so to do this as to make the conformation of the cord explain the performances of which it is capable, appeared to be something beyond our reach. And when we passed from the cord to those cerebral structures the even gross topography of which is the despair of the beginner in anatomical studies, the multiple maze of gray and white matter seemed to frame itself into the letters graven on the gateway of the city of Dis, and bid us leave all hope behind.

What a change has come upon us during the past dozen years, and how great is the hope of ultimate success which we have to-day. Into what at the meeting at Montreal seemed a cloudy masss, in which most things were indistinct and doubtful, and into which each man could read images of possible mechanisms according as his fancy led, the method of Golgi has fallen like a clarifying drop, and at the present moment we are watching with interest and delight how that vague cloud is beginning to clear up and develop into a sharp and definite picture, in which lines objectively distinct and saying one thing only reveal themselves more and more. This is not the place to enter into details, and I will content myself with pointing out as illustrative of my theme the progress which is being made in our knowledge of how we hear and how sounds effect us. A dozen years ago we possessed experimental and clinical evidence which led us to believe that auditory impulses sweeping up the auditory nerve became developed into auditory sensations through events taking place in the temporo-sphenoidal convolution, and we had some indications that as these passed upward through the lower and middle brain the striæ acusticæ and the lateral fillet had some part to play. Beyond this we knew but little. To-day we can with confidence construct a diagram which he who runs can read, showing how the impulses undergoing a relay in the tuberculum acusticum and accessory nucleus pass by the striæ acusticæ and trapezoid fibres to the superior olive and trapezoid nucleus, and onwards by the lateral fillet to the posterior corpus quadrageminum and to the cortex of the temporo-sphenoidal convolution. And if much, very much, yet remains to be done even in tracking out yet more exactly the path pursued by the impulses, while they are yet still undeveloped impulses, not as yet lit up with consciousness, and in understanding the functional meaning of relays and apparently alternate routes, to say nothing of the deeper problems of when and how the psychical element intervenes, we feel that we have in our hands the clue by means of which we may hope to trace out clearly the mechanisms by which, whether consciousness plays its part or no, sounds affect so profoundly and so diversely the movements of the body, and haply some time or other to tell, in a plain and exact way, the story of how we hear. I have thus referred to hearing because the problems connected with this seemed, thirteen years ago, so eminently obscure; it appeared so preeminently hard a task, that of tracing out the path of an ordinary impulse through the confused maze of fibre and cell presented by the lower and middlebrain. Of the mechanism of sight we seemed even then to have better knowledge, but how much more clearly do we, so to speak, see vision now? So also with all other sensations, even those most obscure ones of touch and pain; indeed, all over the nervous system light seems breaking in a most remarkable way.

This great and significant progress we owe, I venture to say, to Golgi, to the method introduced by him; and I for one cannot help being glad that this important contribution to science, as well as another contingent and most valuable one, the degeneration method of Marchi, should be among the many tokens that Italy, the mother of all sciences in times gone by, is now once more taking her right place in scientific no less than in political life. We owe, I say, this progress to Golgi in the sense that the method introduced by him was the beginning of the new researches. We owe, moreover, to Golgi not the mere technical introduction of the method, but something more. He himself pointed out the theoretical significance of the results which his method produced; and if in this he has been outstripped and even corrected by others, his original merit must not be allowed to be forgotten. Those others are many, in many lands. The first, perhaps, was Frithiof Nansen, whose brief but brilliant memoir makes us selfish physiologists regret that the icy charms of the North Pole so early froze in him the bubbling springs of histological research. Of the rest two names stand out conspicuous. If rejuvenescent Italy invented this method, another ancient country, whose fame, once brilliant in the past, like that of Italy, suffered in later times an eclipse, produced the man who, above all others, has showed us how to use it. At the meeting at Montreal a voice from Spain telling of things physiological would have seemed a voice crying out of the wilderness; to-day the name of Ramon-y-Cayal is in every physiologist's mouth. That is one name, but there is yet another. Years ago, when those of us who are now veterans and see signs that it is time for us to stand aside were spelling out the primer of histology, one name was always before us as that of a man who touched every tissue and touched each well. It is a consoling thought to some of the elder ones that histological research seems to be an antidote to senile decay. As the companion of the young Spaniard in the pregnant work on the histology of the central nervous system done in the eighties and the nineties of the century, must be named the name of the man who was brilliant in the fifties, Albert von Kölliker.

When I say that the progress of our knowledge of the central nervous system during the past thirteen years has been largely due to the application of the method of Golgi, I do not mean that it, alone and by itself, has done what has been done. That is not the way of science. Almost every thrust forward in science is a resultant of concurrent forces working along different lines; and in most cases at least significant progress comes when efforts from different quarters meet and join hands. And especially as regards methods it is true that their value and effect depend on their coming at their allotted times. As I said above, neither experimental investigation nor clinical observation nor histological inquiry by the then known methods had been idle before 1880. They had, moreover, borne even notable fruits, but one thing was lacking for their fuller fruition. The experimental and clinical results all postulated the existence of clear definite paths for impulses within the central nervous system, of paths moreover which, while clear and sharp, were manifold and, under certain conditions, alternate or even vicarious, and were so constructed that the impulses as they swept along them underwent from time to time—that is, at some place or other—transformations or at least changes in nature. But the methods of histological investigations available before that of Golgi, though they taught us much, failed to furnish such an analysis of the tangle of gray and white matter as would clearly indicate the paths required. This

the method of Golgi did, or rather is doing. Where gold failed silver has succeeded, and is succeeding. Thanks to the black tract which silver when handled in a certain way leaves behind it in the animal body, as indeed it does elsewhere, we can now trace out, within the central nervous system, the pathway afforded by the nerve cell and the nerve cell alone. We see its dendrites branching out in various directions, each alert to dance the molecular dance assigned to it at once by the more lasting conditions which we call structural, and the more passing ones which we call functional, so soon as some partner touch its hand. We see the body of the cell with its dominant nucleus ready to obey and yet to marshal and command the figure so started. We see the neuraxon prepared to carry that figure along itself, it may be to far-distant parts, it may be to near ones, or to divert it along collaterals, it may be many, or it may be few, or to spread out at once among numerous seemingly equipollent branches. And whether it prove ultimately true or no that the figure of the dancing molecules sweeps always onwards along the dendrites towards the nucleus, and always outwards away from the nucleus along the neuraxon, or whatever way in the end be shown to be the exact differences in nature and action between the dendrites and the neuraxon, this at least seems sure, that cell plays upon cell only by such a kind of contact as seems to afford an opportunity for change in the figure of the dance, that is to say, in the nature of the impulse, and that in at least the ordinary play it is the terminal of the neuraxon (either of the main core or a collateral) of one cell which touches with a vibrating touch the dendrite or the body of some other cell. We can thus, I say, by the almost magic use of a silver token—I say magic use, for he who for the first time is shown a Golgi preparation is amazed to learn that it is such a sprawling thing as he sees before him which teaches so much, and yet when he comes to use it acquires daily increased confidence in its worth—it is by the use of such a silver token that we have been able to unravel so much of the intricate tangle of the possible paths of nervous impulses. By themselves, the acquisition of a set of pictures of such black lines would be of little value. But, and this I venture to think is the important point, to a most remarkable extent, and with noteworthy rapidity, the histological results thus arrived at, aided by analogous results reached by the degeneration method, especially by the newer method of Marchi, have confirmed or at times extended and corrected the teachings of experimental investigation and clinical observation. It is this which gives strength to our present position; we are attacking our problems along two independent lines. On the one hand we are tracing out anatomical paths, and laying bare the joints of histological machinery ; on the other hand, beginning with the phenomena, and analyzing the manifestations of disorder, whether of our own making or no, as well as of order, we are striving to delineate the machinery by help of its action. When the results of the two methods coincide, we may be confident that we are on the road of all truth ; when they disagree, the very disagreement serves as the starting-point for fresh inquiries along the one line or the other.

Fruitful as have been the labors of the past dozen years, we may rightly consider them as but the earnest of that which is to come ; and those of us who are far down on the slope of life may wistfully look forward to the next meeting of the Association on these Western shores, wondering what marvels will then be told.

Physiology, even in the narrower sense to which, by emphasis on the wavering barrier which parts the animal from the plant, it is restricted in this Section, deals

with many kinds of being, and with many things in each. But, somewhat as man, in one aspect a tiny fragment of the world, still more of the universe, in another aspect looms so great as to overshadow everything else, so the nervous system, seen from one point of view, is no more than a mere part of the whole organism, but, seen from another point of view, seems by its importance to swallow up all the rest. As man is apt to look upon all other things as mainly subserving his interests and purposes, so the physiologist, but with more justice, may regard all the rest of the body as mainly subserving the welfare of the nervous system; and, as man was created last, so our natural knowledge of the working of that nervous system has been the latest in its growth. But, if there be any truth in what I have urged today, we are witnessing a growth which promises to be as rapid as it has seemed to be delayed. Little spirit of prophecy is needed to foretell that in the not so distant future the teacher of physiology will hurry over the themes on which he now dwells so long, in order that he may have time to expound the most important of all the truths which he has to tell, those which have to do with the manifold workings of the brain.

And I will be here so bold as to dare to point out that this development of his science must, in the times to come, influence the attitude of the physiologist towards the world, and ought to influence the attitude of the world towards him. I imagine that if a plebiscite, limited even to instructed, I might almost say scientific, men, were taken at the present moment, it would be found that the most prevalent conception of physiology is that it is a something which is in some way an appendage to the art of medicine. That physiology is, and always must be, the basis of the science of healing, is so much a truism that I would not venture to repeat it here were it not that some of those enemies, alike to science and humanity, who are at times called anti-vivisectionists, and whose zeal often outruns, not only discretion, but even truth, have quite recently asserted that I think otherwise. Should such a hallucination ever threaten to possess me, I should only have to turn to the little we yet know of the physiology of the nervous system and remind myself how great a help the results of pure physiological curiosity—I repeat the words, pure physiological curiosity, for curiosity is the mother of science—have been, alike to the surgeon and the physician, in the treatment of those in some way most afflicting maladies, the diseases of the nervous system. No, physiology is, and always must be, the basis of the science of healing; but it is something more. When physiology is dealing with those parts of the body which we call muscular, vascular, glandular tissues and the like, rightly handled she points out the way not only to mend that which is hurt, to repair the damages of bad usage and disease, but so to train the growing tissues and to guide the grown ones as that the best use may be made of them for the purposes of life. She not only heals, she governs and educates. Nor does she do otherwise when she comes to deal with the nervous tissues. Nay, it is the very prerogative of these nervous tissues that their life is above that of all the other tissues, contingent on the environment and susceptible of education. If increasing knowledge gives us increasing power so to mould a muscular fibre that it shall play to the best the part which it has to play in life, the little knowledge we at present possess gives us at least much confidence in a coming far greater power over the nerve cell. This is not the place to plunge into the deep waters of the relation which the body bears to the mind; but this at least stares us in the face, that changes in

what we call the body bring about changes in what we call the mind. When we alter the one, we alter the other. If, as the whole past history of our science leads us to expect, in the coming years a clearer and deeper insight into the nature and condition of that molecular dance which is to us the material token of nervous action, and a fuller, exacter knowledge of the laws which govern the sweep of nervous impulses along fibre and cell, give us wider and directer command over the moulding of the growing nervous mechanism and the maintenance and regulation of the grown one, then assuredly physiology will take its place as a judge of appeal in questions not only of the body, but of the mind; it will raise its voice not in the hospital and consulting-room only, but also in the senate and the school.

One word more. We physiologists are sorely tempted towards self-righteousness, for we enjoy that blessedness which comes when men revile you and persecute you and say all manner of evil against you falsely. In the mother-country our hands are tied by an Act which was defined by one of the highest legal authorities as a 'penal' Act; and though with us, as with others, difficulties may have awakened activity, our science suffers from the action of the State. And some there are who would go still farther than the State has gone, though that is far, who would take from us even that which we have, and bid us make bricks wholly without straw. To go back is always a hard thing, and we in England can hardly look to any great betterment for at least many years to come. But unless what I have ventured to put before you to-day be a mocking phantasm, unworthy of this great Association and this great occasion, England in this respect at least offers an example to be shunned alike by her offspring and her fellows.

MICHAEL FOSTER.

CAMBRIDGE UNIVERSITY.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE work of the Chemical Section of the British Association was inaugurated with the address of its President, Professor Ramsay: 'An Undiscovered Gas.' Starting with a discussion of the history of the various periodic relationships which have been shown to exist among the elements, and of the definition of the properties of unknown members of several of the Groups prior to their isolation, the attempt was made to establish the probability of the existence, and to prophesy the characteristics of an element, as yet unknown, forming a 'triad' with helium and argon. Between fluorine and manganese lies chlorine; between oxygen and chromium, sulphur; between nitrogen and vanadium, phosphorus; between carbon and titanium, silicon, etc. The intermediate element possesses an atomic weight greater, on the average, by 16 units than that of the lightest member of the triad, and less by 20 units than that of the heaviest. Between the lightest and the heaviest, therefore, the difference in atomic weight is approximately 36 units, which is also the difference between the accepted atomic weights of helium (4) and argon (40). "There should, therefore, be an undiscovered element between helium and argon, with an atomic weight 16 units higher than that of helium, and 20 units lower than that of argon, namely 20. And if this unknown element, like helium and argon, should prove to consist of monatomic molecules, then its density should be half its atomic weight, 10. And, pushing the analogy still farther, it is to be expected that this element should be as indifferent to union with other elements as the two allied elements."

Professor Ramsay next reviewed his various efforts to obtain the third member of the helium-argon triad. The most promising method—that of systematic diffusion of the individual gases—failed to show the

presence of any second gas in purified argon; from what has been known as 'pure helium,' however, this process finally isolated a heavier gas which showed the spectroscopic characteristics of argon. No experimental evidence has so far been obtained for a gas with a density of 10.

The address concludes with a discussion of the probable position of argon in the Periodic System, the argument being along the same lines as that previously put forward by the author in his work, 'The Gases of the Atmosphere.' Attention is called to the fact that the differences of the atomic weights of elements following one another in any one Series are quite irregular, varying in the Lithium Series from 1.0 to 3.0, in the Sodium Series from 1.0 to 3.5, etc. Again, in the Silver Series iodine undoubtedly follows tellurium, and yet all the recent determinations of the atomic weight of the latter element unite upon a figure almost a unit above that of iodine; just as density-determinations indicate an atomic weight for argon nearly one unit higher than that of potassium which *follows* it in the System. The author concludes that the relative weights of the atoms of elements, while indicating roughly their position in a perfect Periodic System, are not to be taken as the absolute criterion of their relative sequence. As it is not possible in this short review adequately to discuss this matter, the reader is referred to the author's own statement of the argument.*

In the course of the Meeting Professor Ramsay presented (1) a paper dealing with the process employed in the separation of gases of different densities by fractional diffusion, and (2)—for Mr. Morris Travers—a proof of the fact that the hydrogen evolved on heating minerals in a vacuum is due to the decomposition of water mechanically held and is not present in the form of any other compound. In a paper before the Physical Section he called attention to the great delicacy of refractivity-determinations as a means of deciding upon the purity of light gases.

*SCIENCE, Oct. 1st, pp. 493–502.

The superiority of the oxalate method for the separation of thorium from the other elements with which it is usually associated was demonstrated by Professor Brauner, who also presented the results obtained in a redetermination of the atomic weight of the metal. Professor T. W. Richards reviewed his recent very important work upon the atomic weights of cobalt and nickel, explaining the methods of purification of the salts employed and the apparatus in which they were got ready for weighing. Professor Meslans gave an interesting exhibition of the properties of free fluorine prepared according to the method of Moissan, but in a vessel of copper, instead of platinum, and surrounded by a freezing-mixture of ice and solid carbon dioxide. A very brief paper by Professors Moissan and Dewar on some of the physical constants of liquid fluorine was read by Professor Meldola.

Other papers on inorganic chemistry were those of Mr. E. C. C. Baly, on the formation of a compound when mercury falls in a finely divided state through an atmosphere of oxygen, and which appears to contain the oxygen in the form of ozone; of Dr. C. A. Kohn, on the electrolytic determination of copper and iron in oysters, reminiscent of the recent 'oyster scare' in Great Britain; of Professor W. W. Andrews, on the great increase in the rapidity and accuracy of blowpipe determinations through the use of tablets of plaster of Paris instead of charcoal; of Professor Dunnington, on the occurrence of titanic oxide in soils; and of F. T. Shutt, on analyses of Canadian virgin soils.

In the field of organic chemisty the most interesting paper—perhaps the most striking communication presented at this meeting of

the Association—was that of Professor Nef, on 'The Chemistry of Methylene,' only a portion of which, however, was read. The author, as a result of this and former work, claims among other things to have proved the existence of isomeric acetylenes, one of which is characterized by the presence of a bivalent carbon atom and should therefore be represented by the formula $= C : CH_2$. This substance and its derivatives are remarkable on account of their extraordinary instability, horrible odor and extremely poisonous properties—peculiarities shared in large measure by all compounds of bivalent carbon, among which the author includes the cyanides. By a continuation of the process of removing hydrogen, Professor Nef expects to isolate gaseous and liquid carbon, with molecular weights of 24 and 72, respectively! The publication of the full text of this remarkable paper will certainly be awaited with interest.

As the result of a careful research, Professor Freer brought forward further arguments in favor of the view advanced by Nef for the constitution of the aliphatic ketones and their metallic derivatives. Dr. Lehmann reported the production of benzene derivatives through the reduction of a 1:6 diketone formed by the condensation of benzil with two molecules of acetophenone. A paper on the 'Condensation-products of Aldehydes and Amides' was read by Dr. Kohn. A report of analyses of pre-carboniferous coals was presented by Professor W. H. Ellis.

Professor Roberts-Austen exhibited some photographs of the 'splash' produced by objects falling into molten metals, and intended to show the similarity of behavior in these and other liquids. Mr. Ramage explained a number of photographs of the spectra of minerals and metals, prepared by Professor Hartley and himself. Dr. W. L. Miller exhibited an apparatus designed to determine the vapor-tensions of liquid mixtures. Mr. W. L. T. Addison read a portion of an interesting paper on the formation of crystals. Short papers by Dr. Gladstone and Mr. Hibbert and by Dr. T. Waddell discussed the absorption of Röntgen rays by the light metals. The curious effects produced by certain metals upon a photographic plate when placed in contact with it, or even, in some cases, in its neighborhood, were discussed by Dr. W. J. Russell. In the mutual decomposition of hydrobromic and bromic acids, Professor James Walker finds an interesting case where the application of the theory of electrolytic dissociation furnishes a satisfactory explanation of the course taken by the reaction.

Two papers remain to be mentioned, that of Professor Andrews on 'Reform in the Teaching of Chemistry,' and that of Professor Meldola on 'The Rationale of Chemical Synthesis.' The latter was an attempt to find a common ground upon which the chemist and the physiologist could work, each along his own lines of research, and where, by united judicious effort, more rapid progress could be made into those mysterious regions now withholding from our eager quest so much of vast importance to mankind.

W. W. R.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

The geographers of the United States and Canada have every reason to feel highly pleased with the reception given them at the Toronto meeting of the British Association. Every effort was made to have the visiting geographers feel that their hosts considered them, not guests, but fellow-workers. Nearly one-half of the general committee was composed of residents of North America, and one day was given over to papers concerning Canada and the United States. In all, nearly half of the papers presented were by Americans.

The National Geographic Society, of Washington, D. C., had made especial efforts to have America well represented, and much is due to its efforts. It is, however, to be regretted that there were so many papers of an historical character dealing with the geographic results of the several government bureaus of the United States and Canada, and so few papers on the one branch of geography in which America has done the most in the last few years, namely, Physiography. The absence of many of our best physiographers on official field duties partly accounts for the scarcity of such communications.

The meeting of the Section opened most auspiciously with a goodly attendance at the address of the President, Dr. J. Scott Keltie, Secretary of the Royal Geographical Society, and editor of the *Geographical Journal and Statesmen's Year Book.* Dr. Keltie's careful summary of the geographical results to date, and his outline of possible future work, has already been published in several places, and needs no further comment. The listening American was impressed with the heartfelt compliments that the author paid to the works of several Americans, and to the various United States government bureaus.

In the afternoon of the first day Sir George Robertson gave a very interesting and entertaining account of Kafiristan and the Kafirs, and his life among them. Mr. E. G. Ravenstein reported in brief the results of the Committee on the Climatology of Africa. The committee is continued with a grant of £10 from the Association. The two following papers were brief abstracts of recent investigations of the Physiography and Temperature of Nova Zembla and Spitzbergen.

The second day of the meeting was to have been devoted to educational papers, but there were not enough to fill the program. The day opened with a short paper by the writer on 'Scientific Geography for Schools,' a plea for the assistance of scientists in the planning and execution of geographical courses in schools for all grades. A brief summary was given by the President of the voluminous report of the Committee on Geographical Education, prepared by Mr. A. J. Herbertson. The Royal Geographical Society has within the last fourteen years accomplished a very great reform in geographical education, since the careful study of the conditions by Dr. Keltie brought attention to the matter. Other papers of the forenoon were by Lieutenant-Colonel Bailey, on 'Forestry in India.' Colonel Bailey gave a very interesting account of the present conditions of the forests and the methods of protection necessary, a paper that showed thorough familiarity with the subject at first hand. The indefatigable Recorder of the Section, Dr. Hugh R. Mill, who is also librarian of the Royal Geographical Society, presented a very thoughtful paper on the 'Classification of Geography,' based on the results of his labors in cataloguing. The last paper of the forenoon was by Mr. Vaughn Cornish, on the 'Distribution of Detritus by the Sea,' in which the author considered the ocean processes in much detail.

In the afternoon Professor John Milne, the seismologist, gave a very suggestive and interesting lecture on 'Certain Submarine Changes,' deduced from his study of earthquakes and the breaking of ocean cables. Professor Milne also gave a more popular and inclusive evening lecture before the whole Association, and other papers before the Geological Section, each of which presented many new thoughts of practical use to geologists and geographers. Mr. Ravenstein followed Professor Milne with a detailed account of the result of his studies concerning the Congo and the Cape of Good Hope from 1482 to 1488, and the first rounding of the Cape.

The third day was devoted to the geography of the United States and Canada, and the papers presented were mostly of a historical character, and included an account of the work of the various geographical institutions of the United States, by Marcus Baker; the Work of the United States Coast and Geodetic Survey, by Dr. T. C. Mendenhall; the Hydrography of the United States, by Mr. F. H. Newell; the Geographical Work of the United States Geological Survey, by Mr. C. D. Walcott; Geographical Work of the Canada Geological Survey, by Mr. C. J. White; the Work of the Canada Weather Bureau, by Mr. Stupart, and of the United States Weather Bureau, by Mr. Willis L. Moore.

Professor William M. Davis gave an account of the coastal plain of Maine. This paper epitomized the principles of the physiographic classification of land forms, and gave a careful account of the features of the coastal plain of Maine and its position in the classification, in spite of what appeared to be at first apparent anomalies. Mr. C. E. Lumsden entered a strong plea for the unification of time at sea, and showed the confusion arising from the present systems of time record employed by mariners. The paper of the day drawing the largest audience was that of the explorer and geographer, Dr. J. B. Tyrrell, who gave an interesting illustrated account of the Barren Lands of Canada. Some of the tales of game in this region of difficult traveling, though verified by the camera, were almost incredible.

The session of the fourth day, devoted to physical geography, opened with a large audience to greet the explorer and hunter, Mr. E. C. Selous, who gave a glowing account of the Economic Geography of Rhodesia, based on an intimate knowledge of about a quarter of a century. This paper added many data of value to those brought forth by the report of the Committee on Climatology of Africa, and was full of interest because of the present political condition of South Africa. Other papers of the morning were: 'A Journey in Tripoli,' by J. T. Myres; 'On the Direction of Lines of Structure in Eurasia,' by Prince Kropotkin; 'Potamology as a Branch of Geography,' by Professor A. Penck, and the 'Geographical Development of the Lower Mississippi,' by E. L. Corthell, concerning which it is impossible, for lack of space, to make separate note. Suffice it to say that these papers were among the most scientific of the physical geography papers, and were all of value. The afternoon session was again devoted to North America, with papers on 'Southeastern Alaska,' by Otto J. Klotz; 'The First Ascent of Mt. Lefroy and Mt. Aberdeen,' by Professor H. B. Dixon, and 'Mexico Felix and Mexico Deserta,' by O. H. Howarth. Recent exploration was well represented by the paper on Mt. Lefroy and Mt. Aberdeen, as these peaks had just been scaled for the first time within a few weeks of the meeting.

The last day was devoted to a geographical round up, and could not be classified. The principal paper, read by General A. W. Greely, was 'The Growth and Material Conditions of the United States,' prepared by Mr. Henry Gannett. Professor W. M. Davis spoke on the importance of geography as a university subject.

Though these papers were the only ones that were presented in the Section of Geography, they were not the only geographic papers before the Association; other papers pertaining to physical and anthropological geography were given in different Sections. When we consider the geographic papers *in toto*, we see that the meeting was memorable for the new geographic material presented. New ideas of political or physical geography were not all, however, that the visiting geographers carried away from Toronto. The contact with the

best geographers from abroad was of very great value, particularly to many of the younger men. On every hand good fellowship prevailed, and every one present felt a new impulse to work from the inspiration of the meeting. Many of the visitors took the trip to the western coast after the meeting, on which, according to reports, fully as great results geographically were obtained as at the meeting. Not only must Canada feel a new scientific movement of progress from the meeting, but the United States as well must join in the good to be obtained. The visitors from abroad all agreed that they had gained much from the trip more helpful than mere information. All the Americans trust that they have been able to give in return a part of what they have received, and that this international meeting may help the cause of geography on on both sides of the water.

Richard E. Dodge.

IS THE DENVER FORMATION LACUSTRINE OR FLUVIATILE?

The usual interpretation of stratified deposits refers them to accumulation beneath water, either in the sea or in lakes. But many observers have recognized the ability of rivers to form stratified deposits more or less extensive; hence the mere occurrence of stratification might suggest fluviatile as well as lacustrine or marine origin; and some other sign than stratification would be needed to distinguish among these several conditions of deposition. When fossils are contained in the strata it is commonly easy to determine at least whether they were of salt or fresh water origin; but when without fossils, or when containing only fresh water or land fossils, it may be still a question whether the deposits were formed in lakes or rivers. It has been perhaps assumed that river deposits must be local, while lacustrine deposits may be widespread; but the immense fluviatile deposits of the Indo-Gangetic plain must suffice to free the products of aggrading rivers from narrow bounds. Blandford's account of the vast deposits of waste in long sloping plains at the base of mountain ranges in the interior basins of Persia, as well as the description of similar accumulations in our western country, shows that extensive stratified deposits may be formed in regions where even rivers are not a constant or conspicuous agency; and the believer in the competency of small processes to produce great results if time enough is allowed would find it difficult to set limits to the area or thickness of formation of such origin.

The distinction between true lacustrine sediments and true fluviatile sediments may be made in part by their composition and structure and in part by their fossils. River deposits are of variable sequence, coarse and fine, evenly or unevenly arranged, cross-bedded, ripple-marked and sun-cracked. Mid-lake deposits are of fine texture and even structure, becoming coarse and irregular only near their margin. A characteristic lacustrine fauna, enclosed in mid-lake silts, should be easily distinguished from the mixture of land and water fauna that might be preserved in coarser lake-border deposits or in the coarse and fine strata of normal river deposits. In the absence of a fauna, it might be difficult to distinguish lake-border deposits from river deposits; there might indeed be difficulty in separating lacustrine silts from the fine silts of river flood-plains, if fossils were wanting.

Gilbert's interpretation of some of the newer deposits on the Plains of Colorado near the Arkansas river as of fluviatile origin, and the adoption of his idea by the geologists of Kansas for the eastward extension of the same formations, has recently given practical application to the above generalities. Penck gives in his *Morphologie* a number of European examples of deposits ordinarily called lacustrine, but which

he regards as fluviatile. And on my return home from a sight of the Plains this summer, the receipt of Monograph XXVII., U. S. G. S., on the Geology of the Denver Basin, by Emmons, Cross and Eldridge, suggests a further extension of the discussion. It is particularly with regard to the Arapahoe and Denver formations, in Colorado, that the conditions of origin seem open to another interpretation than that given by these authors ; for it is noticeable that a lacustrine origin seems to have been almost taken for granted, and that a fluviatile origin is not discussed.

The Arapahoe formation is thus introduced: "After an erosion of the Laramie beds * * *, a considerable fresh-water lake was formed and sedimentation again set in. What the exact area of this lake was it is not possible now to determine; * * * whether the lake was continuous along the mountain front or there were several small isolated basins it is as yet impossible to determine. * * * In it were deposited more than 600 to 800 feet of sediments. * * * Of these sediments the lower 50 to 200 feet were conglomerates, the upper 400 to 600 feet arenaceous clays. Vertebrate remains are found in both the conglomerates and the clays, more abundant and better preserved, however, in the latter." (P. 31, 32.)

The interval between the Arapahoe and Denver formations is thus described: "Between the deposition of the Arapahoe and Denver beds a considerable time-interval occurred, during which, as the record of the rocks shows, the Arapahoe lake was drained and the sediments deposited in its bottom were considerably eroded. The movement which caused the drainage of the lake was, as far as present indications go, rather local in its effects, and produced no important deformation of the beds already deposited. * * * This movement was succeeded, after a considerable lapse of time, by a depression sufficient to allow of the formation of a second lake in the Denver basin. * * * The nature of the depression which produced such lakes without admitting marine waters to any extent within the area affected is not readily conceivable, yet its effects are shown to have been widespread by the considerable thicknesses of fresh-water beds consisting largely of eruptive débris." (P. 32.)

The following description is given of the Denver deposits: "The beds deposited in the Denver Lake reached a thickness of over 1,400 feet along the flanks of the mountains, but were probably somewhat thinner toward the middle of the basin. * * * That the Denver beds were deposited in shallow waters is shown by the frequent cross bedding observable both in sandstone and conglomerate, and by the plant remains and standing tree stumps that abound at certain horizons. * * * The Archean material contains large boulders, and the sand grains are angular." (P. 33.)

The vertebrate paleontology of the Denver basin is treated by Professor Marsh in the later pages of the monograph. Nearly all of the typical vertebrate fossils of the Denver region here discussed "were essentially land animals, but not a few of them, especially of the Reptilia, lived near the water and there met their fate. The preservation of their remains was probably, without exception, due to their entombment beneath the waters of the great fresh-water lakes which existed in this region during Mesozoic and Cenozoic time." (P. 525.) The plants discussed by Knowlton are land plants, not lacustrine. The table of invertebrate fossils (p. 78, 79) gives none to the Arapahoe beds, and only six to the Denver beds, all of which imply 'fresh water,' and most of which suggest, according to my colleague, Dr. R. T. Jackson, a fluviatile rather than a lacustrine origin.

Now waiving for the time all reference to

the silty and probably lacustrine deposits on the plains farther east of the mountains than the region here described, may not all the facts of composition, structure and fossil contents, above set forth, be explained as well by fluviatile as by lacustrine conditions? Instead of assuming a series of warping and tilting movements by which lake basins were made and drained, is it not equally legitimate to assume changes of altitude, attitude, climate, drainage areas, etc., by which the rivers of the region altered their behavior from aggrading to degrading? The decision between these alternatives must, of course, not be attempted by an observer away from the ground; but in the meantime the lacustrine origin of the Arapahoe and Denver beds does not seem to be fully substantiated.

If they should finally be shown to be fluviatile, several corollaries that follow from the acceptance of a lacustrine origin would require modification. For example: "Movements of elevation and subsidence, rather of an epeirogenic or continental nature, are indicated by both Tertiary and Pleistocene deposits that have a lacustrine origin, since the present inclination of the plains region, which shows an average descent, in round numbers, of 10 feet to the mile from the foothill region to the valleys of the Missouri and Mississippi, would not admit of the holding of lake waters on its surface." (P. 40.) Fluviatile deposits are, on the other hand, characteristically inclined; and the present slope of the Plains may be not far different from their slope when the Arapahoe, Denver and later beds were formed, if they were spread out by aggrading rivers. I cannot help wondering whether even the peculiar cases of lapsing and overlapping strata, so well worked out by Eldridge about Golden and Boulder, may not find at least some part of their explanation by alterations of fluviatile accumulation and denudation, prompted by changes in grade, climate, drainage, area, etc., rather than depend altogether on movements of elevation and depression. The latter interpretation seems to postulate essential horizontality and rather regular continuity of strata at time of deposition; the latter permits or even requires significant declivity, inequality of thickness and irregularity of overlaps at time of deposition. Indeed, since the question of the fluviatile origin of some of the younger deposits on the Plains has been accepted by geologists familiar with that great field, the possibility of a fluviatile origin for some of the older formations springs to mind. The coarser and non-fossiliferous strata of the foothill belt in particular may, perhaps, be the fluviatile equivalents of finer and fossiliferous strata of lascustrine or marine origin farther eastward on the Plains.

W. M. Davis.

Cambridge, Mass., September, 1897.

THE GRANT SARCOPHAGUS.

On one of the most beautiful sites on the Island of Manhattan stands the mausolæum which the gratitude of a nation has erected to the memory of its illustrious hero.

The altar in this temple of the dead is the sarcophagus, beautiful and imposing in its severe simplicity. The stone out of which it is hewn is a dark red granite, quarried at Montello, Marquette county, Wisconsin.

Concerning the granite of this region Professor Allan D. Conover wrote:* "The rock shows almost no tendency to decompose. It has a medium grain, close texture, is of a bright pinkish color, and without sign of arrangement of the ingredients in lines. These are: Rather large flaked, pinkish, cleavable feldspar, predominating;

* Gannett's Report on the Building Stones of the United States and Statistics of the Quarry Industry for 1880.

somewhat granular, fine, pinkish, translucent quartz, abundant; and greenish-black mica sparsely scattered in blotches made up of very fine flakes. In places thin, light green epidote-colored seams occur.

"Though this granite may be somewhat difficult to obtain in dressable masses, it would probably make a very handsome and durable building and ornamental stone."

Cover and box were quarried from the same ledge of stone; in other words, the original was a monolith in the quarry. For ease of working, however, and in accordance with custom and usage, this monolith was cut up into pieces approximating to finished sizes before being sent from the quarry. About six months were needed to complete the work after it was begun.

It its entirety the sarcophagus weighs seventeen thousand pounds; the largest piece weighs nine thousand pounds. Its entire length is ten feet four inches; it is five feet six inches wide and four feet eight inches deep.

The pedestal on which it rests is made of dark gray granite from Quincy, Mass.

A fragment of the sarcophagus, analyzed by the writer, was found to have the following composition:

	Per cent.
Silica, SiO_2	75.40
Aluminum oxide, Al_2O_3	11.34
Iron oxide, Fe_2O_3	4.16
Calcium oxide, CaO	0.90
Potassium oxide, K_2O	6.44
Sodium oxide, Na_2O	1.76
	100.00.

Its specific gravity (17.5 °C.) is 2.635. The stone is a true granite, accepting as such granite having for its essential constituents quartz and potash feldspar. The feldspar is orthoclase, in which some of the potassium is replaced by sodium.

Mausolæum and sarcophagus were erected under the direction of C. W. Canfield, Esq., of the New England Monument Company, to whose courtesy the writer is indebted for the details given and for the fragment of the sarcophagus subjected to analysis.

FERDINAND G. WIECHMANN.

BOTANICAL NOTES.

BOTANICAL ACTIVITY IN JAPAN.

A RECENT bulletin of the Imperial University of Tokyo (College of Agriculture Bull., Vol. III., No. 3) indicates a degree of activity in the study of botanical problems which must challenge the respectful attention of botanists in Europe and America. It is not too much to say that the papers which appear in this bulletin are of a higher order of merit than are the papers in most of the similar bulletins from American universities, or colleges of agriculture. The titles alone are sufficient to indicate the high scientific value of the bulletin: 'On the origin of sake yeast (*Saccharomyces sake*),' 'Note on a grape wine fermented with sake yeast,' 'On the behavior of yeast at a high temperature,' 'On two new kinds of red yeast,' 'On Brom-albumin and its behavior to microbes,' 'On an important function of leaves,' 'On the behavior of active albumin as a reserve material during winter and spring,' 'On the physiological action of neutral sodium sulphite upon phænogams,' 'On the poisonous action of ammonium salts upon plants.' The most important paper is probably that by M. Suzuki on a function of leaves, in which the author summarizes the results of numerous experiments as follows: "The conclusion seems justified that reserve proteids in the leaves are decomposed into amido-compounds during the night, and the latter are transported from the leaves to the other parts of the plant. The migration of amido-compounds appears to proceed rapidly, as I have found no large quantity in the leaves

gathered in the morning. Thus an important function of the leaves is positively established. This function consists in facilitating the formation of proteids in all parts of the plants by the assimilation of nitrates, yielding thereby amido-compounds which are in all probability better sources for proteid formation than nitrates, in organs poorer in sugar and with a less energetic respiration process. A great advantage is thus gained for the stems, roots and fruits, in which the conditions for nitrate assimilation are less favorable than in the leaves. These amido-compounds produced are either asparagin, which, as I have shown in a former article, can be formed synthetically from ammonium salts as well as from nitrates, or they are the decomposition products of proteids formed in the assimilation of nitrates."

A BROADER STUDY OF LOCAL FLORAS.

It is a hopeful sign of a broadening conception of the work of the local botanist that we see in a recent plant catalogue issued by Professor McClatchie and entitled the 'Seedless Plants of Southern California.' We have so long been familiar with plant catalogues which include nothing more than the flowering plants, often innocently regarded by their compilers as quite completely representing the flora, that it is refreshing to find one in which the flowerless plants are enumerated, while the flower-bearing species are omitted.

Not content with such a departure from time-honored custom, the author prefaces his work with a descriptive synopsis of the classes and orders and freely introduces handy artificial keys to the genera, thus departing still more from the old-style treatment. The synopsis of the plant groups shows that the the author has been more than a mere cataloguer of forms. He has been a student of the groups of which the species are representatives. Accordingly we find that the sequence and limitations of classes and orders are considerably different from those of the ordinary text-books. For this the author has been criticized by some botanists, but we cannot agree with these critics. It will be far better for botany when local students put more rather than less thought into their work, and, instead of deprecating their attempts to make improvements in the general system, we should rather welcome them as hopeful indications that the day of the old-time compiler of bare lists of species, following blindly the prevailing system, is drawing to a close.

In the smaller matters, also, this list is strictly modern, as in the consistent use of metric units in all measurements, the decapitalization of all specific names, the use of trinomials (for varieties), the omission of the comma after the specific name, and the double citation of authorities in the case of species which have been removed from the genera in which they were first described.

Charles E. Bessey.

The University of Nebraska.

NOTES ON INORGANIC CHEMISTRY.

The *Jahrbuch für Mineralogie* contains further investigations, by C. Doelter, on the permeability of minerals for the X-rays. Phenacite (silicate of glucinum) is almost perfectly transparent, even more so than boric acid. Olivine and zoisite are, like calcite, almost opaque; vesuvianite slightly less so. Diopside and hiddenite, like topaz, are half transparent. Sphene is almost opaque, sapphire almost transparnt, the ruby hardly less so. A close relationship appears between the atomic weights and the permeability to the X-rays.

According to L. Davy in the *Comptes Rendus*, all authors who have studied the ancient working of tin in the west of Eu-

rope admit that it was far anterior to the occupation of the country by the Romans, and think that the mines of Abbaretz-Nozay were abandoned by the Gauls about the date of the Roman invasion.

In a pamphlet entitled *Gold Growth* (Cincinnati, The Robert Clarke Co.), Mr. John Jacob Wagner asks: "Does nature transmute silver into gold?" "If it does, can we derive and utilize such hints, from nature's operation, as will enable us to attain artificial transmutation?" The former question he answers in the affirmative in the pamphlet before us; to the latter he promises a reply 'in due time.' The basis of the author's argument is that gold in nature is always found associated with silver, and the ratio of gold to silver is not uniform. If silver never occurs without some gold, it follows that the gold has grown from the silver, and the varying proportions found in different mines are due to the length of time the growth has been going on. Hence in the older rocks the proportion of gold to silver is greater then in the later rocks. Pure gold can be separated from silver alloy; but the 'fine silver' resulting invariably contains gold. The inference is that the silver is 'growing' into gold. This pamphlet belongs to a class of writings by no means rare, the efforts of laymen to clear up facts and theories which are far from clear to specialists who have devoted their lives to them. Granted that the premises of the writer are true, his deductions would have no weight to a chemist. He finds not merely silver and gold occurring together, but many other elements always associated with each other. If gold 'grows' from silver, why not potassium from sodium, or bromin from chlorin, etc.? The only difficulty with the theory is that at present there is absolutely no evidence of facts to support it, and the wisest chemists hesitate to philosophize on the problem of the genesis of the elements. It may be questioned if books, such as that before us, have any value; certainly they have not from a scientific standpoint.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE DEDICATION OF THE YERKES ASTRONOMICAL OBSERVATORY.

The University of Chicago has made very complete arrangements for exercises in connection with the dedication of the Yerkes Astronomical Observatory, to continue throughout the present week. The arrangements are as follows:

October 18, Monday.

2:30 p. m. Fourth Annual Meeting of the Board of Editors of the *Astrophysical Journal.*

4:30 p. m. Opening session of conferences. Informal talks on recent investigations, including:

Assistant Professor F. L. O. Wadsworth (Astrophysicist, Yerkes Observatory), on the application of Diffraction Phenomena to Astronomical and Astrophysical Measurements.

Dr. G. F. Hull (Professor of Physics, Colby University), on Electric Radiation.

7:30 p. m. Assistant Professor Wadsworth will demonstrate with the 40-inch Yerkes telescope the application of interference methods to astronomical measurements.

Professor Burnham will show selected double stars with the 40-inch telescope.

October 19, Tuesday.

9:00 a. m. Second session of conferences.

Dr. Henry Crew (Professor of Physics, Northwestern University), on the Source of the Characteristic Spectrum of the Metallic Arc.

Dr. Henri Deslandres (Astrophysicist, Paris Observatory), on a subject to be announced later.

Dr. W. J. Humphreys (University of Virginia), on the effect of Pressure on Wave-length.

Professor James E. Keeler (Director of the Allegheny Observatory), on the Spectra of Stars of Secchi's Third Type.

Professor H. C. Lord (Director of the Emerson McMillin Observatory, Ohio State University), on Researches in Stellar Spectography.

Professor Carl Runge (Director of the Spectroscopic Laboratory, Technische Hochschule, Hannover), on Oxygen in the Sun.

Professor Ormond Stone (Director of the Leander McCormick Observatory, University of Virginia), on the Great Nebula of Orion.

2:15 p. m. Address on the Yerkes Observatory by Professor George E. Hale, Director.

3:00 p. m. Professor Hale and Mr. Ellerman will show various solar phenomena with the 40-inch Yerkes telescope, including the chromosphere and prominences, the reversal of the H and K lines in prominences and faculæ, the duplication of the D_3 line, etc.

Experimental demonstrations will be given in the Observatory laboratories as follows:

Experiments with the rotating arc, Professor Crew.

Analysis of electric radiation by means of the interferometer, Professor Hull.

The effect of pressure on wave-length, Dr. Humphreys.

Measurements of wave-lengths in the infra-red spectrum, Assistant Professor Wadsworth.

Demonstrations in the Optical Shop, and in the Instrument Shop.

7:30 p. m. Professor Barnard will show with the 40-inch Yerkes telescope:

N. G. C. 224 (Andromeda Nebula).
N. G. C. 598.
N. G. C. 1976 (Orion Nebula).
N. G. C. 2245 (cometary nebula).
N. G. C. 2392 (planetary nebula).
N. G. C. 6543 (planetary nebula).
N. G. C. 6618 (Swan nebula).
N. G. C. 6720 (annular nebula).
N. G. C. 7009 ('Saturn' nebula).
N. G. C. 7078 (globular cluster).
R. Leporis (Hind's crimson star).
Selected variable stars.

The 12-inch refractor and 24-inch reflector will be used for miscellaneous observations.

OCTOBER 20, WEDNESDAY.

Professor George C. Comstock (Director of the Washburn Observatory, University of Wisconsin), on Determination of Stellar Parallax, and on Investigations of the Lunar Atmosphere.

Professor C. L. Doolittle(Director of the Flower Observatoy, University of Pennsylvania), on the Latitude Work of the Flower Observatory.

Father Hedrick (Astronomer, Georgetown College Observatory), on the Photochronograph.

Professor H. S. Pritchett (Director of the Observatory, Washington University,) on Personal Equation in Longitude Determination.

Dr. Charles L. Poor (Associate Professor of Astronomy, Johns Hopkins University), on a New Form of Mirror for Reflecting Telescopes.

Professor J. K. Rees (Director of the Columbia University Observatory), on the Variation of Latitude and the Reduction of the Rutherfurd Photographs.

Assistant Professor F. L. O. Wadsworth, on a Photographic Meridian Circle.

Professor E. E. Barnard (Astronomer, Yerkes Observatory), on Astronomical Photography.

Father Hagen (Director of the Georgetown College Observatory), on An Atlas of Variable Stars.

Professor G. W. Hough (Director of the Dearborn Observatory, Northwestern University), on Jovian Phenomena.

Professor G. W. Myers (Director of the Observatory, University of Illinois), on the System of β Lyræ.

Professor Simon Newcomb, on a subject to be announced later.

Professor E. C. Pickering (Director of the Harvard College Observatory), on the Work of the Harvard College Observatory.

7:30 p. m. Professor Hale will show the spectra of the following objects with the 40-inch Yerkes telescope:

N. G. C. 1976 (Orion Nebula). *α* Lyræ.
N. G. C. 7027. *α* Tauri.
Alcyone. *α* Orionis.
D.M. 30° 3639.

OCTOBER 21, THURSDAY.

8:30 a. m. Departure from Chicago, of the special train.

9:30 a. m. Final session of conferences.

Dr. Kurt Laves (the University of Chicago), on the Teaching of Theoretical Astronomy in America, and on Jacobi's Investigations in Theoretical Astronomy.

11:30 a. m. Formal Presentation and Acceptance of the Yerkes Observatory.

1. Address: 'The Importance of Astrophysical Research and the Relation of Astrophysics to other Physical Sciences.' Professor James E. Keeler, Sc.D., Director of the Allegheny Observatory.
2. Presentation. Mr. Charles T. Yerkes.
3. Acceptance on behalf of the Trustees. The President of the Board of Trustees.
4. Acceptance on behalf of the University. The President of the University.
5. Prayer. Charles Kendall Adams, President of the University of Wisconsin.

1:00 p. m. Luncheon.

2:00 to 3:30 p. m. Inspection of the Yerkes Observatory.

OCTOBER 22, FRIDAY.

10:00 a. m. Inspection of the Ryerson Physical Laboratory and other buildings of the University of Chicago.

In the Ryerson Laboratory Head Professor Michelson and Associate Professor Stratton will demonstrate the effect of a magnetic field on radiation, and exhibit an interferential comparer and a new form of harmonic analyzer.

1:00 p. m. Luncheon given by the President of the University.

3:00 p. m. Address: 'Aspects of Modern Astronomy.' Professor Simon Newcomb, LL.D.

7:30 p. m. Banquet.

THE LABORATORIES OF THE BRITISH GOVERNMENT.

THE Revenue Laboratories of the British government for chemical examination and analysis have just been housed in a new building erected adjacent to King's College Hospital. From the London *Times* we take the following facts regarding the building and its equipment: It occupies a site of about 7,900 square feet, and its various rooms, 38 in number and capable of accommodating about 100 workers, are distributed over three floors and a basement. The building externally is befittingly simple in character, and, with the exception of the entrance, which faces Clement's Inn, is altogether devoid of any attempt at ornamental treatment. On the ground floor are situated the office of the Principal Chemist, the Deputy Principal, a small reference library, the research laboratory, the crown contracts laboratories, and the laboratory for the examination of food and drugs sent by magistrates under the Adulteration Act of 1875. Samples of imported butter taken by customs officers at the port of entry at the instance of the Board of Agriculture are also examined in this laboratory, as are samples of fertilizers and feeding stuffs referred in accordance with the Act of 1893.

The first floor is wholly reserved for the examination of alcoholic products and manufactured tobacco. The alcohol laboratory, arranged for 32 workers, is a lofty, well-lighted room, with conveniently-disposed work-tables fitted with various contrivances for the rapid and accurate examination and analysis of brewing materials, worts, beers, wines, tinctures, medicated wines, compounds, etc. In the same laboratory is conducted the examination of the wood naphtha required for the methylation of alcohol. Round the room are placed the balances needed for the estimation of density, etc., and under each window is a table for the clerical work of the analysts, special arrangements being made for the keeping and preservation of the official registers. Immediately adjoining are the polariscope room and an artificially cooled chamber, capable of holding some thousands of samples pending examination. Close to the entrance of the main laboratory are the offices of the superintending analysts, each fitted with a working bench and with presses for the custody of microscopes and special apparatus. Next to these are the tobacco rooms. In one of these the incineration work, required for the determination of sand and inorganic matter, is conducted in muffle-furnaces fired by gas. The estimation of moisture in manufactured tobacco, instituted in 1887, are also conducted in this room, the samples being heated in a series of jacketed steam ovens, arranged to work continuously night and day. The main tobacco laboratory is fitted with appliances for the examination of manufactured and the so-called 'offal' tobacco for determination of drawback and for the detection of fraudulent or improper admixtures.

On the second floor are placed a number of special rooms, a museum of specimens of adulterated foods and other products, a small class-room for the instruction of supervisors, a type-writing office, and a room for the preparation of micro and other photographs.

In the basement are situated rooms for the standardization of the instruments employed in the revenue service, and laboratories for the chemical and bacteriological examination of waters sent by the Prison Department of the Home Office, the Board of Trade, Office of Works, and other public departments. There is also here provision for operations requiring a high temperature, as in furnaces, oil and air baths, etc.; a small mechanical laboratory, rooms for the storage of chemicals, apparatus and stationery, and of samples required to be

preserved either for purposes of reference or pending prosecutions.

AMERICAN MATHEMATICAL SOCIETY.

BEGINNING with the present academic year, the regular meeting of the American Mathematical Society will, as we have already noted, be held on the last Saturday of October, February and April, instead of monthly from October to May as heretofore. The annual meeting for the election of officers takes place in the last week in December, falling this year on Wednesday, December 29th. Each meeting will now extend through two sessions, beginning at 10:30 a. m. and 2.30 p. m. As a result of the arrangement, it is believed that the individual meetings will become of greater prominence and interest, and that the members of the Society will be afforded a better opportunity for mutual acquaintance and scientific discussion. The first meeting of the Society under the new program will be held on Saturday, October 30th, in Room 301 of the Physics Building of Columbia University, New York City. The following is a list of the papers thus far entered for presentation:

MORNING SESSION.

1. Dr. G. W. HILL: 'Intermediary orbits in the lunar theory.'

2. Mr. P. R. HEYL: 'Notes on the theory of light on the hypothesis of a fourth dimension.'

3. Dr. E. O. LOVETT: 'Note on the fundamental theorems of Lie's transformation groups.'

4. Professor CHARLOTTE ANGAS SCOTT:

5. Professor E. W. BROWN: 'Note on the steering of an eight-oared boat.'

AFTERNOON SESSION.

6. Professor R. S. WOODWARD: 'On the cubic equation defining the Laplacian envelope of the earth's atmosphere.'

7. ———— 'On the integration of a system of simultaneous linear differential equations.'

8. Professor MANSFIELD MERRIMAN: 'The probability of hit on a target when the probable error in aim is known; with a comparison of the probabilities of hit by the methods of independent and parallel fire from mortar batteries.'

9. Professor A. S. CHESSIN: 'Note on hyperelliptic integrals.'

DURING the past year a section of the Society has been organized with headquarters at Chicago. The meetings of the section, like the summer meeting of the Society, usually extend through two days, and are held in the Christmas holidays and in April.

THE October number of the *Bulletin* (Vol. 7, No. 1) has just been issued, and contains, beside the usual 'Notes' and 'List of New Publications,' the report by the Secretary of the Summer Meeting at Toronto, articles on 'Regular Triple System,' by Professor E. H. Moore; on 'Collimations in a Plain with Invariant Quadric or Cubic Curves,' by Professor H. S. White; on 'A generating Function for the Number of Permutations with an Assigned Number of Sequences,' by Professor Frank Morley; and a review of Koenig's 'La geometrie réglée et ses applications,' by Dr. Virgil Snyder.

GENERAL.

THE fifteenth annual Congress of the American Ornothologists' Union will meet at the American Museum of Natural History, New York, on the evening of November 8th, and will continue in session on the three following days.

THE directors of the Philadelphia museums propose holding in October of next year an exposition of the raw and manufactured products of the United States. It will be in conjunction with the next meeting of the advisory board of the museum, which will be attended by many foreign delegates.

MEMORIAL exercises in honor of the late General Francis A. Walker were held by the Massachusetts Institute of Technology, in Boston, on October 14th. There were more than 3,000 people present in Music Hall, including many delegates from educational and scientific institutions. Addresses were made by Governor Walcott and Senator Hoar.

PROFESSOR J. M. SCHAEBERLE has been appointed acting director of Lick Observatory in the place of director Edward S. Holden, whose resignation is noted elsewhere in this issue. It is said that either Professor Schaeberle or Professor Davidson will probably succeed Professor Holden in the directorship.

LORD KELVIN sailed for England on Saturday, after a week filled with engagements, including

a reception by the American Philosophical Society, a reception at Princeton and a luncheon at Columbia University.

DR. JOHN GUITERAS, of the University of Pennsylvania and the U. S. Marine Hospital Service, has returned to Philadelphia, after having made a thorough study of the yellow fever in the South, and will present an exhaustive report of his inspection to Surgeon-General Wyman.

MR. W. G. MACMILLAN, lately lecturer in Mason College, Birminghom, has been appointed Secretary of the British Institution of Electrical Engineers.

PROFESSOR GUNDELFINGER, of the Botanical Institute of Darmstadt, has been awarded the gold medal for merit of the Munich Academy of Sciences.

WE note with much regret the death of Charles E. Colby, since 1889 professor of organic chemistry in Columbia University. He was born in Lawrence, Mass., in 1855, and graduated from the School of Mines of Columbia College in 1877. Professor Colby's work was hampered by deafness and ill-health, but he was a chemist of unusual ability, and his death is a serious loss to Columbia University.

DR R. P. H. HAIDENHAIN, since 1859 professor of physiology at Breslau, died on October 13th, aged sixty-three years. He is the author of important contributions to experimental physiology, his work on secretion being perhaps the most valuable.

WE also regret to record the deaths of Dr. Edmund Drechsel, professor of medical chemistry in the University of Berne, aged fifty-six years, and of Dr. Stoll, formerly director of the Pomological Institute at Proskau, aged eighty-four years.

A DISPATCH to the daily papers stated that during an ascent of Mount Ararat, Armenia, by members of the recent Geological Congress, Dr. Stoeber, a professor of medicine, was frozen to death.

KITES sent up on October 15th, from the Blue Hill Observatory, surpassed the record of September 19th, recorded by the director, Dr. Rotch, in a recent issue of the JOURNAL, by more than 1,500 feet. They carried the meteorological instruments to a height of 10,900 feet above the hill top, or 11,500 feet above sea level. The kites were sent up at 3:50 o'clock in the afternoon and reached the highest point by six o'clock. At that altitude the temperature was 43°, while it was 73° at the ground.

DURING the course of a lecture at Montevideo, on October 15th, Dr. Sanarelli stated that the serum he has obtained from the animals with which he has been experimenting is effective against yellow fever, and that it will very probably cure yellow fever in human beings.

IT is reported that the Cavendish Sporting Expedition through Africa arrived safely at Kikuiu on August 5th, and started for Zanzibar on August 15th. The expedition has crossed from the Gulf of Aden by somewhat the same route as that of Dr. Dondaldson Smith, and is said to have made valuable geographical explorations.

IT is doubtless known to all our readers, from the daily press, that the British Foreign Office has agreed to a scientific conference on the seal fisheries by delegates from the United States, Great Britain and Canada. Professor d'Arcy Thompson will, it is reported, leave at once for the United States.

A BERLIN despatch to the New York *Sun* states that the International Leprosy Conference, which has been in session for a week, expects to conclude its deliberations on Saturday. Comparatively little has been added to the knowledge of the disease, except what was contained in a statement by Dr. Babes, of Bucharest, that leprosy bacilli were found in great abundance in mucus, which, accordingly, was a dangerous channel of infection. Another debate resulted in a concurrence of opinion that leprosy was not specifically a skin but a general disease. There was much discussion as to the treatment of the disease, especially of experiments with serum. All the experiments had been without result, except in one case, where the outcome is in doubt. The conference appointed a commission to prepare plans for the formation of an international leprosy society. Professor Virchow is the president of the commission, and Dr. Dyer, of New Orleans, is a member.

THE Audubon Monument Association of New Orleans is collecting money for a monument of Audubon to be placed in the park named after him in New Orleans. For this purpose the Association offers to sell a memorial volume giving an account of Audubon's life, prepared by Mrs. M. F. Bradford.

A CHEMICAL society has been formed at Brown University. It held its first meeting on October 5th, when an address was given by Professor John Howard Appleton on 'Recent Discoveries in Chemistry.'

FOUNDERS' Day at Lafayette College was celebrated on October 20th, the exercises being a tribute to Professor T. C. Porter, who this year retires from active service after sixty years devoted to the natural sciences, which he has taught at Lafayette College for thirty years. According to the program addresses were to have been made by Professor Nathaniel L. Britton, of Columbia University, the director of the New York Botanic Garden, on 'The Progress of Systematic Botany in North America,' by Professor William B. Scott, professor of geology in Princeton University, on 'Thirty Years of Geological Progress in North America,' and by Dr. John M. Crawford, of the class of 1871, lately Consul-General to St. Petersburg, on 'Dr. Porter as Pioneer in Finnish Literature.'

THE Commissioners of Works and Public Buildings, London, offer to distribute this autumn, among the working classes and poor inhabitants of London, the surplus bedding-out plants in Hyde and Regent's Parks and in the pleasure gardens of Hampton Court.

The Auk states that a unique and exceedingly appropriate memorial to the late Henry Davis Minot consists of a park of some fifty acres in extent, recently transferred by his four brothers, William, Charles S., Robert and Lawrence Minot, in accordance with the wishes of their father, the late William Minot, to the trustees of public reservations in Massachusetts, to be maintained as a wild park, 'for the use of the public forever.' This park, to be known as Mount Anne Park, consists of a tract of about fifty acres of beautiful woodland near the village of West Gloucester, Mass. It includes Mount Anne, or Thompson's Mountain, the highest point on the North Shore, some 225 feet above the sea—a pine-clad, granite summit in the midst of a forest wilderness. The park is otherwise charmingly diversified, being a spot of exceptional natural beauty.

THE Lowell textile school has opened its second year with an attendance of 230 students, twice as many as last year. Classes this year will be formed by Professor W. W. Crosby, of the Massachusetts Institute of Technology, Professor Fenwick, of Umpleby, and others.

MR. C. W. ANDREWS, of the British Museum, has been sent by the trustees to Christmas Island, the expenses of the expedition being defrayed by Dr. John Murray, for the purpose of making collections of the fauna for the British Museum. Christmas Island, about 200 miles south of Java, is only inhabited by some twenty-two persons, but it is soon to be used by a phosphate company, hence the importance of making collections of the fauna and flora, which are unusually interesting, a large proportion of all the species being endemic.

MESSRS. MACMILLAN & Co., Limited, have removed from their familiar building near Covent Garden to St. Martin's street, London, W. C., where they have erected a magnificent building of Portland stone, with a frontage of 106 feet in Whitcomb street, 99 feet in St. Martin's street and 24 feet in Blue Cross street. The editorial and publishing offices of *Nature* are removed to the new site, as also the British agency of SCIENCE.

THE valuable collection of vertebrata made by Mr. A. C. Savin from the forest bed, Norfolk, has been purchased by the British Museum (Natural History).

THE Sunday *Inter-Ocean*, Chicago, has published in successive issues a series of articles on the collection of fossils of Mr. W. T. E. Gurley, from 1893 to 1897 State Geologist of Illinois. In addition to tens of thousands of duplicates and unclassified specimens, the collection is said to contain over 14,000 species, all labeled and in good condition, divided about as follows: Types of batrachians and reptiles, 65; fishes (entire), 145; fish teeth, spines and bones, 765; insects and arachnids, 66; myriapods and crustaceans (exclusive of trilobites),

230; trilobites, 425; annelids, 40; rhizopods and polyzoans, 10; sponges, 60; bryozoans, 760; corals and allied forms, 1,525; lamellibranchs, 1,625; gasteropods, 1,800; cephalopods, 850; pteropods, 60; brachiopods, 3,175; cystids, 35; echinoids, 175; blastoids, 150; star fishes, 50; crinoids, 1,250 (fully 700 with heads and arms complete); hydrozoa, 90; diatoms, 25; plants, 400. The collection, as we have stated, is for sale and it is hoped that it may be secured for some institution in Illinois.

AN item in the daily papers to the effect that M. Becquerel has recently been admitted with honors to the École polytechnique, Paris, is of sufficient interest to be quoted here, in view of the fact that he is the son, grandson and great-grandson of eminent physicists. M. Henri Becquerel, his father, is the distinguished professor of physics in the École polytechnique; A. E. Becquerel, the grandfather, formerly professor of physics in the École des Arts et Metiers, is well known for his important contributions to physics, chemistry and meteorology; the great-grandfather, A. C. Becquerel, director of the Paris Museum of Natural History, was a physicist of great eminence, whose discoveries in electro-chemistry are known everywhere; an uncle, L. A. Becquerel, was also a man of science of distinction.

DR. W. F. MORSELL sends us the following further decisions of the United States Board on Geographic Names: In Kansas it should be *Junction*, not Junction City, as generally understood; so, also, in the same State, Empire City and Osage City are similarly abbreviated by the Board. A dozen or more decisions affect names in New York State, but they are unimportant. The creek, mountain and pond in Essex county is *Vanderwhacker*, not Van der Whacken, etc., and the river in the Adirondack region is *Sacundaga*, not Sacandaga, Sacondago, etc., as variously written. The channel north of Staten Island is Kill *van* Kull, not Kill *von* Kull, being of Dutch origin, not German. In Gilmer county, Georgia, there is a postoffice which the Board writes *Santaluca*. This is not from the Spanish, as one would suppose, but from the Cherokee Indian language. Among foreign names, on which there are a few decisions, the Board decides on *Austria-Hungary*, and also favors *Burma* (not Birmah nor Burmah). The German city should be *Mainz*. The German government has protested to our Consuls for spelling the word in the French way—Mayence.

THE Macmillan Company have just published the course of lectures by 'The Founders of Geology' given last winter by Sir Archibald Geikie to inaugurate the lectureship in the Johns Hopkins University founded by Mrs. Williams in memory of the late Professor Williams. In the preface to the volume Sir Archibald Geikie speaks of geological work and geological opportunity in America as follows: "Renewing old friendships with some of the veterans of the science, and forming fresh ties of sympathy with many younger workers who have come to the front in more recent years, I could not but be impressed by the extraordinary vitality which geology has now attained in the United States. Every department of the science has its enthusiastic votaries. Surveys, professorships, museums, societies, journals in almost every State, are the outward embodiment of the geological zeal that appears to animate the whole community. This remarkably rapid development of the science has not arisen from any influence derived from without, but springs, as it seems to me, from the marvellous geological riches of the American continent itself. In minerals and rocks, in stratigraphical fulness, in paleontological profusion, in physiographical illustrations, the United States have not only no need to borrow materials from Europe, but in many important respects can produce examples and materials such as cannot be equaled on this side of the Atlantic. Had the study of the earth begun in the New World instead of the Old, Geology would have unquestionably have made a more rapid advance than it has done. The future progress of the science may be expected to be largely directed and quickened by discoveries made in America, and by deductions from the clear evidence presented on that continent."

THE *American Geologist* publishes two extraordinary letters from the person who has been appointed State Geologist of Missouri. One of these letters concludes as follows:

"I will now remind you that 'every dog has his day. This is my day and the time is not far distant when your client will wish he had carried his tracks along with him. That you and he have run up against the wrong man is only a question of time. You can make the most of your opportunity and I will pursue the even tenor of my way."

Such occurrences are discouraging, even though it is certain that their duration will be but brief. We are of the opinion that it is the duty of the Geological Society of America, even though it should cost each member one-tenth of his time and of his income for one year, to see that the facts of the case are brought before the Legislature and the people of Missouri.

THE outgoing Vice-Chancellor of Cambridge University stated in a valedictory address to the members of the Senate that the gifts to the museums and laboratories during the past year include a cast of the famous specimen of *Iguanodon bernissartensis* presented by his Majesty the King of the Belgians, a refrigerating machine for experimental purposes presented by Mr. T. B. Lightfoot, a valuable collection of dried plants presented by Mrs. C. Packe, a very important library of geological books presented by Professor Wiltshire, M.A., of Trinity College, who has on previous occasions shown himself to be a most generous benefactor to the University, and two collections of great historical interest presented by the family of the late Charles Darwin.

ACCORDING to the *Statist*, the yield of gold for 1896 was about £45,000,000, against an average of £21,738,000 for the period of 1881–90. For 1896 the production by fields was as follows: United States, £10,800,000; Australasia, £8,988,000; Transvaal, £8,604,000; India, £5,911,000; Russia and other countries, £10,-697,000—or a total of £45,000,000. The grand aggregate of the gold production since 1850 inclusive is, in round figures, £1,163,000,000, or, approximately, 300,000,000 ounces of gold.

UNIVERSITY AND EDUCATIONAL NEWS.

THE Academic Freshman class at Yale University is said by the New York *Evening Post* to number 58 less than last year, while there is an increase of 15 students in the Scientific School. There is, this year, an increase of about 300 students at the University of Michigan, chiefly in the law department, and of over 100 at Columbia University. A decrease of about 50 students in the undergraduate department of Brown University is reported.

THE New York *Tribune* states that the University of Missouri receives $23,023 from the estate of the late John C. Conley, under the operation of a law recently passed by the Legislature which provides that if a man dies leaving no father, mother or direct lineal descendant a certain per cent. of his estate, excluding any amount left for charitable or religious purposes, must go to the State University.

DR. R. C. CHRISTIE, formerly professor at Owens College, Manchester, has given the College the whole of his share in the residuary estate of the late Sir Joseph Whitworth, estimated at £50,000. The College has also received gifts of £20,000 for the erection of a physical laboratory and £6,000 for its maintenance and of £1,500 towards the erection of a museum.

THOSE who last winter objected to the action of Cornell University in deciding to follow the example of the great English and other American universities and award the degrees A.B. and A.M. for scientific as well as for classical studies probably do not read this JOURNAL. Otherwise we should like to call their attention to the fact that Cornell in its short history has conferred forty-seven kinds of degrees, and ask whether it is an advantage to increase or decrease the numbers of kinds of degrees awarded for liberal studies.

THE Board of Overseers of Harvard University have concurred with the president and fellows in their votes changing the title of Hugo Münsterberg from professor of experimental psychology to professor of psychology, and of William James from professor of psychology to professor of philosophy.

DR. WILLIAM S. CARTER, of the University of Pennsylvania, has been elected professor of physiology in the University of Texas.

DR. CHARLES W. HARGITT, professor of biology in the College of Liberal Arts of Syra-

cuse University, will have charge of the work in embryology in the College of Medicine.

DR. EDWIN F. NORTHRUP has resigned from the professorship of physics in the University of Texas. The students' paper of the University remarks: "During the brief thirteen years that the University of Texas has been in operation there have been no less than five professors in this school. Their tenure of office has been short, and, in the main, their departures abrupt."

DISCUSSION AND CORRESPONDENCE.

RESIGNATION OF THE DIRECTOR OF LICK OBSERVATORY.

AFTER a continuous connection with the Lick Observatory for 23 years and a service at Mount Hamilton since 1888, I have terminated my official relations with the Observatory, to take effect on December 31, 1897. My address after October 1st will be as below:

EDWARD S. HOLDEN.

SMITHSONIAN INSTITUTION, WASHINGTON., D. C.

THE BOSTON PLANS FOR A NEW YORK BOTANICAL GARDEN.

TO THE EDITOR OF SCIENCE: I wish to call your attention to an inexcusable piece of bad taste in the last number of *Garden and Forest.* That excellent journal was from its foundation edited by the late William A. Stiles, to whom the public park system of New York is so greatly indebted. It is, however, conducted, whatever that may mean, by Professor C. S. Sargent, director of the Arnold Arboretum. The last number of *Garden and Forest*, in an editorial notice of Mr. Stiles, gives as his crowning work the following:

"It was his forethought and technical knowledge which have modified and delayed the schemes of the men who in their zeal for a botanic garden are willing to deface, unnecessarily, Bronx Park, and could his life have been prolonged this most valuable and beautiful of all the rural possessions of the city might, perhaps, have been spared for the best enjoyment of the public."

It is well known that Professor Sargent's interference with the well matured and carefully prepared plans for the New York Botanical Garden, as enlarged upon in the daily press, has lessened the public appreciation of an institution so important for the scientific and general welfare of the City. It is commonly reported here that Professor Sargent does not wish New York City to possess a botanic garden superior to the one directed by him. This report is doubtless incorrect, but it will certainly not be silenced by using an obituary notice of a friend in the manner indicated.

You will, I hope, excuse me from giving my name for publication, and will permit me to state that I am in no way connected with the New York Botanical Garden.

SOURCE OF THE FAMOUS THETFORD LIMBURGITE.

NEARLY half a century ago Dr. Oliver Payson Hubbard, while a member of the faculty of Dartmouth College, discovered large boulders of olivine basalt in Thetford, Vt., and discussed their probable derivation from basaltic areas in Canada.

Some of these boulders have found their way as museum curiosities to Chicago, Washington, New York and New Haven. They are particularly noted for their large rounded masses of olivine and crystalline, grayish green, glassy pyroxene.

In 1894 Dr. E. O Hovey presented to the scientific world, through the columns of the 'Transactions of the New York Academy of Sciences,' valuable information concerning the petrography of these basaltic boulders and referred them to the limburgite division of the family.

Professor J. F. Kemp has commented upon the striking resemblance of olivine diabase to these boulders, and discussed the improbability of a meteoric origin.

It has constantly been conjectured that their source was to the northward, since Vermont is in a region of extensive glaciation from that direction, yet geological research had failed to reveal their origin until last August.

During the summer of 1896, while engaged in field work in stratigraphical geology, I encountered many dikes of diabase rich in olivine, and others of the same microscopical appearance

as the typical camptonite in the Pemigewassett Valley, N. H.

By diligent investigation it was my good fortune last August to discover in the locality of these ramifying dikes and the famous Corinth copper mines an extraordinary dike of limburgite, from 6 to 10 feet in width, and penetrating the calciferous mica schist toward the west for more than half a mile.

This limburgite bears individual crystals of olivine two to three inches in length and one to two inches in breadth. A single specimen has been placed in the museum of Dartmouth College containing a crystal of olivine two and one-half inches by one and three-fourths.

Some of the smaller crystals by the oxidation of the iron have become converted into limonite or hematite; others have gone over into serpentine, while a bit of calcite derived from the contiguous orthorhombic pyroxene or the basic plagioclase feldspar is occasionally seen in the cavities once filled by the original olivine crystals.

As the locality is to the northward in the exact direction of the moving ice, and at a distance of only about twenty miles from the famous Thetford boulders, it seems evident that Corinth, Vt., was their original habitat.

MORE DICTIONARY ZOOLOGY.

Some time ago I called attention in your columns to the inaccurate zoological information given by a recently published dictionary. I have just had occasion to examine the *Encyclopædic Dictionary* (Philadelphia, 1896) and should like to ask how the editors explain the following eccentricities:

(1.) *Snail.* "*H. aspera* is also eaten." *Helix aspersa* is the snail intended; *H. aspera* is a totally different snail, found in the West Indies.

(2.) *Slug.* "*A. agrestis*, the Red Slug." There is no *Arion agrestis*. The article, with its errors, appears to have been taken (without acknowledgments) from an old edition of *Chambers' Encyclopædia.* If the editors had examined the recent edition of that standard work, published several years before 1896, they would have found a different account.

(3.) *Coccus.* The species assigned to *Coccus* belong to seven perfectly distinct genera; and no author in the last twenty-five years who has given any study to these insects has used the last century classification of the *Encyclopædic Dictionary.*

The editors of dictionaries will have to realize that if their zoological definitions and articles are to be accurate and up-to-date they must employ specialists to write or revise them. Until they do so, zoologists should make it their business to call attention to the misrepresentation of their science in works which the public is asked to receive as models of accuracy.

LANTERN TRANSPARENCIES.

To the Editor of Science: Those who have occasion to have copies of engravings or pictures of any kind made for use with the lantern may be glad to know that such may be printed from the plates used in ordinary printing if sheets of thin transparent celluloid be taken. Gelatin also may be used. The latter is liable to roll up more or less and needs to be protected by inclosing between glass plates of the ordinary size for lantern slides. Celluloid will not trouble so much in that way, yet it is best to mount such pictures in the same way. Photographic half-tones show very well indeed, the fine meshing not being enough magnified nor dense enough to be noticed upon the screen at the distance of a few feet. Such copies need cost but a few cents apiece if the electro can be got to print from, and if celluloid be used without the glass cover perhaps one cent would be the full cost. I enclose a couple of samples that you may judge of the quality of such pictures.

DANGERS OF FORMALIN.

To the Editor of Science: Now that the use of formalin for preserving objects for dissection is becoming so common, I think a word of warning as to the danger involved in the use of even attenuated solutions should be given. It is doubtless a matter for the medical faculty to

explain and limit, but as no one has spoken from their ranks a word from a layman may be of service.

The handling of objects which have been preserved in a 4 % solution kills the outer cuticle and appears to have a paralyzing effect on the sub-cuticular nerve terminations. Repeated use demoralizes the skin very badly. The vapor or minute drops arising in dissection from the objects manipulated is liable to cause serious affections of the eye. We have just heard from a recent colaborator of the museum who has narrowly escaped the loss of one eye, and is probably condemned for life to the use of glasses as a result of dissections of slugs preserved in formalin. Irritation of the mucous membrane of the air passages has probably been observed by every one who has used this preservative.

SCIENTIFIC LITERATURE.

Hallucinations and Illusions. A Study of the Fallacies of Perception. By EDMUND PARISH. London, Walter Scott; New York, Charles Scribner's Sons, 1897. Pp. 390. Contemporary Science Series, Vol. XXXI.

The present volume is a rewriting, by the author, of his German monograph, published about three years ago; and this in turn grew out of his examination, for the Munich Psychological Association, of the cases collected in Germany for the 'International census of Waking Hallucinations in the Sane'—a project initiated and vigorously promoted by the English Society for Psychical Research. While there is an extensive literature on some one or another of the many ramifications of the general subject of illusions—particularly contributions of cases illustrative of certain special kinds or causes of illusion—there is a conspicuous lack of more comprehensive and systematic treatises covering the general field, both descriptively and with the purpose of presenting these various forms of fallacious perception from some unifying theory or principle.

It can hardly be said that the author has succeeded in filling this gap, although the road which he set out to survey has been covered with accuracy and originality. Comparison is at once suggested with the older volume of Sully on 'Illusions,' which, though far less scientifically thorough and necessarily lacking in the explanations and conceptions that have grown out of recent research, is none the less more comprehensive in scope and more philosophical as well as attractive in treatment. The general reader will still find more enlightenment as to the nature of illusions in the work of Sully than in that of Parish, although he can find no abler treatment of certain phases of this study than the latter work offers. To begin with, Dr. Parish's definition of his topic rules out the consideration of that interesting group of normal deceptions of the senses—commonly known as optical illusions and the like—which are so significant for the study of sense-interpretation and perception. Indeed, instead of conceiving an illusion as any form of psychological process which happens to be erroneous he aims to establish a type of perception, at times normal and at times abnormal, as the basis of all hallucinations and illusions. This underlying principle is found to be that of dissociation, "a state in which, indeed, generally speaking, the consciousness is normal, but where the association-paths of a more or less complicated system of elements are wholly or partially blocked." Hallucinations and illusions "are just as much sensory perceptions as the so-called 'objective' perceptions." The dream state is an extreme state of dissociation, and as such hallucinations and illusions become the stuff that dreams are made of; in insanity and nervous fatigue; in moments of emotional excitement as well as of rapt attention; under the influence of drugs and particularly in hypnotic states, the conditions are favorable for that distortion and inhibition of the normal association-paths which Dr. Parish holds to be the starting point of fallacious perception.

This conception has much in its favor; it makes it natural to find a considerable number of hallucinations among the sane and in the waking state; it certainly binds together the various forms of semi-abnormal and morbid conditions under which illusions most commonly occur; it is equally adaptable to the explana-

tion of the experimental phases of the topic, such as hypnotism, automatic writing, crystal vision ; and it further gains strength by the inherent weakness of former theories, both 'centrifugal' and 'centripetal,' which attempted to present the illusion as a reversal of the physiological process of true sensation or of some of the cortical and subcortical functions. In spite of these advantages, it cannot be claimed that this or any other theory at present serves any other purposes than that of a temporary framework for a building that is yet to be planned. The physiologist and the pathologist, as well as the alienist and psychologist, must all expend very much more planning and labor upon the foundations before a really suitable superstructure can be possible. More literally, the present status of the subject seems hardly likely to yield a true explanation of the illusory process, a satisfactory account of what really goes on in nerve and brain-cell as well as in the field of mental processes when we see with the mind's eye.

This criticism is offered in no disparagement of Dr. Parish's essay. His attempt to bring order out of chaos is most commendable, and for what is, perhaps, the most striking example of the fruitful nature of his conception the reader may be referred to is the ingenious analysis of 'audible thinking' as the analogy of 'automatic writing' which is given in Chapter VIII.

A considerable portion of the volume is devoted to the presentation of the statistics of hallucinations of the sane and their critical discussion, one phase of this discussion being devoted to those hallucinations which are supposed to be 'veridical' or to serve as proofs of 'telepathic' agencies. This portion of the work is most commendable; the sincerity and painstaking devotion of the compilers of the census and other evidence for telepathy are fully appreciated and acknowledged. But the verdict is 'not proven,' with a strong indication in favor of the negative. The extreme complexity and variety of the sources of error, the inherent defects of the logical cogency of the evidence, and the likelihood of the applicability of other and more normal forms of explanation, are all admirably set forth and together form a line of argument which the numerically strong but logically weak accumulations of cases are not likely to overcome. This careful sifting of obscure sources of error, this technical and thorough analysis of the real nature of these elusive hallucinatory conditions, makes rather difficult reading, but it is the only profitable mode of dealing with the subject.

This lack of popular attractiveness in Dr. Parish's work is probably a desirable feature, at least in some respects. The interest in this and kindred topics has been entirely too much centered upon the explanation of individual experiences and the proving of this or that hypothesis. The prevalent popular attitude is that of the man who has had an experience and wants it 'explained,' even to the most trifling detail, and who, in default of such explanation, feels warranted in disparaging the science that so dismally fails when practically tested, and in accepting any hypothesis, however unnatural or unscientific, which seems to cover his case. It is well to impress this individual with the inherent difficulty of such study, with the technical acquisitions needed to qualify one to form any opinion on the matter, and with the true statistical and impersonal method of dealing with 'cases.' The principle that in the progress of science the interest in the abnormal precedes and only slowly gives way to an interest in the normal has recently been well emphasized and illustrated ;* it is as true in psychology as in other sciences. The superficial interest in much that is 'psychic' doubtless belongs to this earlier stage of culture and will probably give way to a better comprehension and appreciation of man's normal psychology. A lesser form of utility of the present volume is in disparaging an undesirable and uncritical interest in the abnormal.

JOSEPH JASTROW.

Manual of Bacteriology. By ROBERT MUIR, M.A., M.D., F.R.C.P., Ed., Lecturer on Pathological Bacteriology, and Senior Assistant to the Professor of Pathology, University of Edinburgh; Pathologist, Edinburgh Royal Infirmary ; and JAMES RITCHIE, M.A., M.D., B.Sc., Lecturer in Pathology, University of

* By W J McGee, SCIENCE, Vol. VI., p. 413.

Oxford. With one hundred and eight illustrations. Edinburgh and London, Young J. Pentland ; New York, The Macmillan Company. 1897. Price, $3.25.

Bacteriology as a distinct domain in biology has developed with amazing rapidity within the past few years, owing partly to the stimulus which a new technique has afforded, partly to the keener appreciation of the importance in biology of a knowledge of the simpler life process down near the border line ; but more than all, perhaps, to the fact that among the bacteria are a few forms which cause a large part of the acute diseases of men and animals. For the latter reason bacteriology has been a foster child of medicine and, in the minds of many, is only one of the congeries of disciplines which we call medical science. But as our knowledge grows, we realize that the relationships of bacteriology to medicine embrace but a small part of bacteriological lore, which reaches far away from disease and deals with most significant phases of organic life throughout the earth.

In reality, the book before us is not a manual of bacteriology, but a manual dealing with those phases of bacteriology which concern disease, or medical bacteriology.

About one-fourth of the text relates to the general subject of the morphology, biology and technical methods of study of the bacteria ; a few pages are devoted to non-pathogenic microorganisms, while the remainder is given to a general consideration of the relationship of bacteria to disease, and to an epitomized description of the more important infectious diseases, especially of man. A discussion of the significant subject of immunity follows and, finally, in a series of appendices, certain of the important infectious diseases are reviewed whose etiological factors are not bacterial or are as yet unknown.

There are many manuals of medical bacteriology in many languages and of all grades of excellence, and this phase of bacteriology is growing so rapidly that new books and new editions are necessary.

This book of Muir and Ritchie is a most valuable addition to the list and might wisely supersede many of the current elementary works. It is a well-digested, well-arranged and wisely and clearly expressed epitome of the medical phases of bacteriology and of the bacteriological phases of disease. The historical glimpses of recent studies upon some of the infectious diseases aid greatly in the comprehension of the present point of view regarding them and afford clues which, in connection with the judiciously limited bibliography at the end, may lure and guide the student into a deeper acquaintance with his theme. The illustrations, over one hundred in number, are largely from photo-micrographs and the half-tone reproductions are for the most part as satisfactory as the technical limitations will permit.

The book is altogether excellent, and is really a model epitome of a difficult and complex theme, a safe and stimulating guide to the student and a boon to the busy practitioner who must read as he runs, if he reads at all.

*SPECIAL EXPLORATIONS IN THE IMPLEMENT-BEARING DEPOSITS ON THE LALOR FARM, TRENTON, N. J.**

BY permission of Professor F. W. Putnam a number of geologists and archæologists were invited by me to conduct independent investigations on the Lalor farm in Trenton, N. J., with a view to verifying the conclusions at which he had arrived concerning the age of the artifacts found in the gravel at that place. As a result of the invitation, Mr. H. C. Mercer, Professor Arthur Hollick, Dr. H. D. Kümmel and Professor William Libbey met with me upon the ground, and we availed ourselves of the facilities afforded us by Mr. Ernest Volk, who has been for several years engaged in explorations in the vicinity of Trenton, under the direction of Professor Putnam, in the interests of the Peabody Museum, Cambridge, Mass.; the Columbian Exposition, of Chicago, and the Museum of Natural History of New York City. I was upon the ground the 25th, the 26th and the 28th of June, and September 13th and 14th, 1897. At this time Mr. Mercer was present every day but the 13th of September, and Professor Hollick every day but the 28th of June and the 14th of September, while Dr. Kümmel and Professor Libbey were present for only a single day.

* This paper will be followed by others on the same subject.—ED.

The farm on which such generous privileges have been granted by the Misses Lalor is situated on the terrace upon which the city of Trenton is built, about a mile below the city, overlooking the Delaware river from the edge of the terrace, which here descends abruptly to the flood-plain of the Delaware, about forty feet below. That this farm is within the limits of the so-called 'Trenton gravel' is conceded by every one, and is clearly evident from a gravel pit which has been recently opened not more than three hundred yards to the north. In this pit, which has been worked to a depth of about twenty feet, the general sand and gravel are very distinctly stratified, with the lines of bedding and cross-bedding perfectly distinct up to within three or four feet of the surface. Many boulders, some of them two or three feet in diameter, occur in the lower part of the deposits. A large pile of boulders which had been thrown aside by the workmen well illustrates the observation early made by Professor Cook and Professor Shaler, that the material of the Trenton gravel is almost entirely derived from the upper part of the valley of the Delaware river, and is to that extent local material.

There is but one theory entertained by geologists at the present time concerning this gravel, which is, that it is a delta deposit made by the glacial floods which came down the river from the melting of the ice which formed the Belvidere terminal moraine, about seventy miles above Trenton. Through that distance the gradient of the river is about three and a-half feet to the mile, and the valley is narrow, so that the abundant floods of that time could easily bring down the excessive amount of *dêbris* released by the melting ice. On reaching tide-water and a broader valley at Trenton the swollen streams of that epoch rapidly built up the fifty-foot delta terrace upon which the city stands. This terrace is from two to three miles in diameter, upon the New Jersey side, and wherever excavated shows substantially the same phenomena described in the pit adjoining the Lalor farm, which is about the middle of the special enlargement of the deposit from north to south from which the gravel received its name.

The excavations made by our party were upon the summit of this delta deposit, beginning from the bluff where it faces the river valley to the west, and which breaks down to the level of the flood-plain, forty feet below, with as steep a descent as the gravel would naturally maintain, the slope being now covered with a luxuriant growth of forest trees.

As our investigations were made with reference to verifying the conclusions of Mr. Ernest Volk, it is proper to state the main results of his work. Mr. Volk has carefully dug over the area stretching back from this bluff for a width of about three hundred feet and a length of something like twenty-five hundred feet. Over all this area he has sunk trenches a little over three feet in depth, and carefully noted the evidences of human occupation, together with the character of the deposit and the depth at which the artificial objects have occurred. All this material gathered by him is to be found carefully labelled, but for the most part unreported upon, in the museums above referred to in our first paragraph. Mr. Volk's work has shown that the upper twelve inches of this surface contains more or less signs of vegetable mould, and a very large number of chips and chipped implements made from flint and jasper, with occasional chipped pieces of argillite. Many other indications of the ordinary occupation by Indians also occur in this upper foot of soil; such as pieces of pottery, the bones of animals which had been used for food, and pieces of charcoal. Occasionally, also, there are pits running to a depth of two or

three feet in which are similar objects down to the bottom.

But in the compact undisturbed sand from one foot below the surface through the two feet or more of the lower part of the trenches Mr. Volk reports that he has found no pottery or charcoal or chipped fragments of jasper, flint or quartz; but that he has found, sparingly scattered throughout the entire mass, many chipped fragments and implements made from argillite, these occurring frequently near the bottom of the trenches, three feet and more below the present surface and two or more feet below ordinary signs of recent disturbance.

At the first visit our own work consisted in the digging of one long trench from near the edge of the bluff back through a distance of twenty-one and a-half feet. Its width was three and three-quarters feet, and its depth a little over three feet. This was immediately north of the ground which has been explored by Mr. Volk. We also dug three other pits, one being about twenty feet farther north, which was $7\frac{3}{4}$ x $4\frac{1}{2}$ feet; another, thirty feet east of the second, which was six feet square; a fourth, one hundred feet still farther east, and on ground about one foot higher, which was four and a-half feet square.

After careful examination we fixed upon fifteen inches as the limit of probable or possible ordinary disturbance, and had all the superincumbent soil removed from the trenches to that depth. We then had narrow excavations made two feet lower or to a total depth of forty inches, in some cases going still farther down. Having prepared a smooth perpendicular surface, the work was subsequently done by carefully scraping off the face of the excavation with a trowel, and when any object of stone was encountered, all were called to witness it in place before removal. In this way a total amount of three hundred and twenty-five cubic feet of the deposit was carefully examined. This is equivalent to a trench forty feet long, four feet wide and two feet deep; this being the lower two or more feet of the material removed.

Number of Objects Found.—As a result of this examination during the first visit, there were found in the lower two feet of undisturbed soil fifteen chipped fragments or implements of argillite all covered with a deep patina, two thick flakes of jasper and three of quartz, with a few broken stones. There were found and counted also between three hundred and four hundred pebbles ranging from the largest, which was $8\frac{1}{2}$ x $4\frac{3}{4}$ x $2\frac{1}{2}$ inches, down to numerous ones the size of a French pea. Many of them were from one to two inches in diameter. The implements were scattered pretty evenly through the entire mass of gravel. The upper five inches contained four; the second five, seven; the third five, four; the fourth five, five. Besides this there were six battered or broken pebbles, showing artificial origin, but all these were in the upper six inches of our stratum. Of the quartz and flint flakes, two were found in the upper four inches, two from ten to twelve inches down, and one at a depth of eighteen inches.

The Character of the Strata.—Beginning at the top, there is first a stratum of fifteen inches to be excluded. The upper seven inches of the stratum under consideration consists of compact sand in which there are no signs of bedding or disturbance of any sort.

Below this occurs, over most of the area, a reddish, clayey band, about a-half inch thick, which extends in a wavy line, often thinning out so as to be almost imperceptible.

Below this is a stratum of yellowish sand, similar to the first, about six inches thick.

Below this is a second continuous reddish band slightly waved, but far less so than

No. 1, and about two inches thick, thinning out, however, in places to half an inch or slightly less.

Then occurs another stratum of yellowish sand, about four inches thick.

Still lower comes reddish clay,* ten inches thick, partly divided by an irregular stratum of sand, two or three inches thick, running through the middle of it. In some places, however, the clay bands coalesce, and the sand continues along the line in lenticular masses. This clay stratum rests upon the more completely washed sand and gravels which form the great mass of the terrace.

Analysis of these Strata.—The predominant material in the entire thickness examined is sand, but there is mixed with it a varying amount of clay and iron, both being specially concentrated in the red bands. I have had specimens from these strata analyzed to determine the relative amount of clay, sand and iron contained in them. The specimens were first thoroughly and repeatedly soaked and shaken in water, which was poured off immediately, carrying everything which could be held in suspension, and leaving the sand thoroughly washed. After being allowed to settle twenty-four hours, the water was siphoned off and the residue thoroughly dried. This was then compared in bulk with the residue of sand which had also been dried. All the specimens were treated in a similar manner. The results were, beginning at the top:

1st sand stratum, 18% suspended matter; 2d sand, 16%; 3d sand, 14%; underlying sand, 7%. Of the red bands, 1st red stratum, 24% suspended matter; 2d red stratum, 27%; 3d stratum, 27%; 4th (or lower part of 3d) stratum, 37%. The amount of iron contained in the fine sediments so far as analyzed was as follows: from the 2d sand, one-half of one per cent. of the whole amount; of the 2d red stratum, one and one-half per cent. of the whole amount, and the same for the 4th red stratum. These red bands, therefore, are not to any appreciable extent segregations of iron. The iron scarcely more than suffices to give the color. The analysis shows, therefore, that these red bands contain from 25% to 33% more clay than is found in the interstratified strata of sand.

While the water-worn pebbles were distributed more or less through the entire mass, they are specially abundant in and below the second, third and fourth reddish clayey accumulations. These pebbles vary in size, as has been said, from those several inches in diameter down to small pieces of gravel. Pebbles from one to two inches are numerous. The largest one referred to was imbedded in the clayey stratum, No. 2, just as if dropped into the clay and pressed nearly through it, crowding lower down two or three smaller ones which underlay it. This was found in the longer trench, thirty-two inches below the surface, or seventeen inches below our selected zone of doubt. This was about three feet distant from the locality of one of our best-formed chipped argillite scrapers, which occurred three inches lower down in the deposit, and beneath the clayey stratum. As I personally removed with my trowel all material in this section, I know that the clayey stratum containing the large pebble was continuous and unbroken, not only between the pebble and the point directly over the argillite implement, but for two or three feet upon the other side, and that pebbles, large and small, were frequently struck by the trowel along the entire distance.

The implement above referred to was located carefully and photographed by us. The first clayey band over it was here about two inches thick and so compact as to give distinct special resistance to the trowel

* Throughout I use clay as signifying simply sediment so fine that it is held in suspension in water for an appreciable time.

wherever it was struck. Its level was twenty inches below our zone of doubt, or thirty-five inches below the surface. Upon our last visit, however, two well-formed argillite implements were found at still greater depth, and if possible in still more unequivocal position. One of these, found by Professor Hollick, was in the main trench more than twenty feet farther east. This was, also, below the second clayey band, which is here nearly ten inches thick. The implement was three feet five inches below the surface, or twenty-six inches below the arbitrary line we had fixed as our zone of doubt. The order of strata was as follows: one foot, disturbed soil; eighteen inches, compact yellow sand; first wavy reddish clayey band, one-half inch; yellow sand, two inches; second reddish clayey stratum, with inclosed lenticular sand patches, ten inches; sandy layer, five inches, containing the implement; reddish clayey band, five inches. Below this, without any signs of unconformity, were several successive alternating strata of sand and reddish clayey material to the total depth dug, six feet nine inches. There was every indication that the entire deposit up at least to the upper wavy reddish clayey stratum was built up by a continuous process of water deposition, the upper portion representing the waning cycles of deposition characteristic of floods which were reaching their limit both by reason of increased elevation of the flood-plain and of a diminution of the water supply.

Eight feet north of this implement, across the end of the trench, with the strata continuous between, Mr. Volk had previously photographed another argillite implement in place one inch lower than this and beneath almost exactly the same succession of strata. Again, on the face of one of our earlier pits farthest from the bank, about forty feet disant from this one, we found on the second visit and photographed, and Mr. Mercer took out with his own hands, a well-formed argillite implement three feet three inches below the surface, or two feet below our arbitrarily chosen line of doubt. There were two of the clayey bands above this, the order being closely similar to that described in the trench. The second of the clayey bands, which is here about two inches thick, contained a pebble more than two inches in diameter, which was pressed down into the stratum as if by its own and the superincumberent weight. On removing the pebble the clay adhered to it, but was not cemented to it. It could all easily be removed with the fingers. Two or three feet east of this implement were the marks of the tap-root of a tree which had penetrated all the strata to a depth of something over two feet. It was perfectly easy to distinguish the course of this root, but there were no other signs of such disturbance around the face of the exposure in the vicinity of any of the implements described.

Extent of the Reddish Clayey Bands.—To determine the extent of these deposits and the manner of their formation, pits were dug at three points, from two hundred to five hundred feet farther in from the edge of the bluff. Two of these were upon a slightly elevated ridge, from two to three feet higher than our main trench, being the highest portion of the plain. The other was in the center of a shallow basin, towards which there was a gradual slope in every direction, it being from two to three feet lower than the trench and about two hundred feet away. In all these pits the succession of strata was similar to those in the main trench, with this difference, however, that the reddish clayey bands were encountered several inches lower down in the center of the basinlike depression than upon the higher elevations. This effectually disposes of the theory that the slight irregularities in the surface were produced by wind action. If the elevations were wind accu-

mulations the sand would be thicker there than in the depressions, but the opposite was the case. The slight irregularities of the surface, therefore, are the result of original motor deposition and not of wind action.

Observations upon other portions of the delta terrace revealed the same condition of things. In the gravel pit already referred to, about three hundred yards to the north, the succession in the upper three or four feet exposed is substantially the same. The clayey bands are distinctly apparent, and the whole structure is conformable. In this pit there occurs, and was photographed by us, a thick deposit of fine sand near the bottom, containing thin wavy bands of stratified clay, very similar to the upper one described in our main trench. Again, about a mile distant, toward the southeast, near the park, an excellent exposure of the terrace shows the same succession. With this, also, agrees the description given by Mr. Volk of his explorations on the same terrace in 1891, at a point about half way between the park and the present explorations. (See Proceedings of the A. A. A. S., Vol. XLII., 1894.) In describing the strata, he says: "The soil in this place consists of nine inches of black or subsoil, tilled land, overlying an undisturbed sandy loam composed of quartz sand, colored by iron and mixed with a yellow soil, the sediment of muddy water, the whole having a light yellow color. Three feet below the surface is a somewhat uneven stratum of red clay mixed with sand."

From all this it is clear that this deposit, up at any rate to the upper line of reddish clayey band, is part and parcel of the Trenton gravel.

A most natural explanation of the deposition of these successive strata of sand and clayey bands is at hand in the closing floods of the glacial period which confessedly built up the terrace to within a few inches of several of the implements found in place. All the phenomena can easily be accounted for by the forces then known to be in operation. The floods accompanying the close of that stage of the glacial period which formed the terminal moraine crossing the river at Belvidere brought down the *débris* from the melting ice until the delta terrace was built up to a height of about forty-seven feet. This, all readily admit. But it is easy to see that as the delta grew higher, and the material accessible to floods diminished, the closing deposits would consist of finer material, the conditions being somewhat like those of ordinary flood-plains, only in this case the forces were more extraordinarily variable and vast in their proportions. In the last stages of this epoch we may well suppose that during the months of July, August and September the waters running over this delta terrace were occasionally swollen enormously, though the elevation overflowed was such that any large masses of boulder-laden ice were prevented from sweeping over it, such as did during the earlier stages of the deposit. These floods would easily distribute large quantities of sand along the edge of the terrace of the main stream, extending back for an indefinite distance or to the slightly higher deposits that had previously been made, and this under conditions so uniform that several inches might be accumulated without signs of bedding. On the subsidence of the floods the clayey strata would naturally accumulate, as shown in these deposits.

But how did the implements become incorporated in the strata? By a process which is perfectly natural and credible. During the larger part of the year, when the melting of the glacial ice was proceeding at a slow rate, vast bars and abandoned channels of the main pebbly deposits of sand and gravel would be exposed, affording to the aboriginal inhabitants a choice

field for procuring argillite boulders, with an occasional one of quartz or jasper, from which to make their favorite implements; while the conditions connected with the head of tide-water doubtless made it then, as later, a favorite hunting and fishing ground. Few things have ever impressed me so much as the abundance of life of all sorts at the head of the inlets, both in Alaska and Greenland, into which large glaciers pour their currents of ice-cold water. The implements and chips lost by the natives on these temporarily abandoned stretches of gravel and sand bordering the main current are the ones mingled with scattering pebbles which were swept into their present position upon the Lalor farm by the subsequent floods of the season.

But this condition of things did not remain long. After the flooded Delaware ceased to receive superabundant glacial *dêbris* and an excessive supply of water from the melting ice it not only ceased to build up the terrace, but began speedily to cut and enlarge its present channel, leaving the surface of the delta terrace forever after undisturbed by its action. The terrace is now about forty feet above the flood-plain. Thus we have a natural and perfectly credible method for accounting for the phenomena in question.

It is, however, not only incumbent to provide an adequate cause for such phenomena, but we are in duty bound to give sound reasons for excluding other hypotheses which may be supposed to account for the facts. One hypothesis is that the clay band No. 2 has been produced by segregation, and so may have been formed over the implements found underneath it since their deposition. But the stratum contains only a slight amount of iron in excess of that found throughout the entire sand deposit. There still remains the excessive amount of clay which characterizes the stratum. It can scarcely be possible that that was segregated over so extensive an area after the whole had been deposited. Besides there must be something to account for the slight excess of iron which characterizes the red stratum. It is not only slightly excessive in amount above what is found in the accompanying sand, but is different in color; that being yellow and this red.

The suggestion that this clayey stratum No. 2 is an old wind-blown surface encounters several insuperable objections.

1. Its extent and uniformity are greater than could be obtained by a wind accumulation.

2. It contains large numbers of pebbles too great for removal by winds. As already mentioned, one of these was several inches in its longest diameter, and many were over an inch in diameter. To the suggestion that these may have been brought upon the surface by human agencies at the same time that the chipped flakes were lost, it can be answered that many of these were too small to have offered any inducement to anybody to have brought them up into that place, and they are scattered through the formation so uniformly that they indicate distribution by natural agencies; while their occurrence in the clayey stratum points to water, and not to wind, for their distribution. Especially significant were the two or three small pebbles underneath the large one which lay as if pressed by the weight of the larger pebble into and almost through the clayey stratum.

To the suggestion that these pebbles had been brought up from the lower strata by overturning of trees, it is to be said that if that was the case it must have been before the formation of the clayey stratum since that by actual observation was continuous and undisturbed for a distance of many feet on either side of many of these pebbles.

To the theory which would account for the iron in the stratum through the oxida-

tion of the vegetable accumulation occurring upon the surface, it is to be replied that this would not account for the accumulation of clay, but rather it needs the accumulation of clay to arrest the soluble iron in its downward progress. Whatever may be true of that upper and more wavy film of reddish material, it cannot well be maintained that stratum No. 2 is of a different origin from that of the thicker strata 3 and 4, the last of which rests directly on the acknowledged glacial gravel. In case of these it cannot be maintained that they are the results of a progressive oxidation proceeding from the surface downwards, since they are distinctly separated by the strata of yellow sand. There must have been something in the original deposition to have determined the relation of these differently colored strata to each other, and that original stratification has not been to any great extent disturbed by subsequent agencies.

If these red bands are the results of oxidizing agencies connected with vegetable deposits, they must still be placed long anterior to the accumulation of vegetable mould which is now upon the surface; for in many cases Indian pits are found in which the vegetable mould is entirely unaffected by oxidizing agencies; and, as this farm is known to have been occupied by the whites two hundred years, we have a partial measure of the slowness with which vegetable matter decomposes in this soil.

Furthermore, if the action of tree roots, worms and other small animals were so great in breaking up and destroying the lines of stratification two or three feet below the surface, as some have supposed, these clayey strata must be very recent, else they would have been completely obliterated. But their integrity is a complete answer to the theory that the soil down to a depth of four feet is everywhere necessarily disturbed through the lapse of long periods of time. In the present case every attempt to account for the clayey strata 2, 3 and 4 otherwise than by the agency of water is beset with insuperable difficulties. There are none of the marks of those other supposed agencies left to indicate their activity. Whereas, with the acknowledged floods of water rising to within a few inches of these deposits, it is easy to believe in the extension of this agency in building up the deposits of the superincumbent fifteen inches. If any one denies this natural and easy explanation he is bound to bring forth reasonable evidence to the contrary. To adduce complicated hypotheses involving inadequate and unknown causes of which there are no signs present, is not sufficient.

The evidence that the implements found below stratum No. 2, forty-one inches below the present surface, and only five inches above the action of acknowledged glacial floods, belong to the deposits of the glacial floods is sufficient, I believe, to convince any one who comprehends all the facts. At any rate, it is in the highest degree hazardous to assert that the problem of their age is insoluble, and that no trustworthy inference concerning it is possible. For a short time the facts can remain open for the observation of others. Let any one who is in doubt visit the locality and see for himself.

Professor Libbey of Princeton University spent the afternoon of September 14th with us on the ground when all the exposures were open to inspection. These he photographed and carefully examined with reference to all the questions involved. In respect to them he writes as follows: "Princeton, September 20, 1897. I take pleasure in putting on record my opinion with reference to the deposits which we studied together last week. There is no doubt in my mind as to the origin of the deposits in which the various implements were found. The lower gravel layer immediately below is undoubtedly due to

water action, and I cannot believe that the banded region composed of sand heavily mixed with clay could have been laid down in any other way than those just below. Certainly no wind action can ever be held responsible for such level and uniform deposits over such an area, but it might rather be explained by a change in level affecting the velocity of the current—in fact, I believe the existence of this bed can be explained only in this way."

G. FREDERICK WRIGHT.

OBERLIN, September 20, 1897.

PROFESSOR RUDOLPH HEIDENHAIN.

THE announcement of the death of Professor Rudolph Heidenhain, though not entirely unexpected, will call forth in physiological circles a note of deepest regret. It brings to memory the names of Brücke, Helmholtz, Karl Ludwig and Emil DuBois-Reymond, members of that coterie of brilliant scientists whose unusual ability for many years attracted to the German laboratories students of medicine from every part of the civilized world. And with these names are largely associated the remarkable transformation and progress which physiological science has experienced since the days of Johannes Müller.

Rudolph Peter Heinrich Heidenhain was sixty-three years of age at the time of his death, having been born Marienwerder, January 29, 1834. The elder Heidenhain was a physician, and it was not strange that the young man should inherit an enthusiasm for the natural sciences; it is told, in fact, that his interest in the work to which his life was devoted was early aroused by the reading of Volkmann's 'Haemodynamik,' which had just been added to the father's library. Heidenhain pursued the usual university medical studies at Königsberg, Halle and Berlin, receiving his degree at the latter place in 1854 with a dissertation entitled 'De nervis organisque centralibus cordis cordiumque ranae lympaticorum.' As assistant to Du-Bois-Reymond, the following three years were devoted to investigations in muscle physiology, a series of studies being published in 1856. In 1857 Heidenhain qualified at Halle as 'Privatdocent' in physiology, with a thesis entitled 'Disquisitiones criticae et experimentae de sanguinis quantitate in mammalium corporis exstantis'; two years afterward, in 1859, at the early age of twenty-five, he accepted the chair of physiology and histology at Breslau in Silesia, a position which he occupied until his death. Heidenhain obtained many official distinctions during his academic career, and among these the Harveian medal with which he seemed especially pleased; he was a member of numerous learned societies, and for many years enjoyed the title of 'Geheimer Medicinalrat.'

The advent of Heidenhain to Breslau and to the institution in which, years before, Purkinje had been active, was followed by a series of physiological researches continued almost uninterruptedly until the past year. These contributions have been marked not alone by the originality with which the subjects have been treated, but especially by a deep insight into the problems presented and a thoroughness of investigation and devotion of energy as untiring as it was characteristic. The results of these labors have had so important an influence in determining certain chapters of physiology as taught to-day that it may, perhaps, be permitted to present a few fragments of Heidenhain's work and to indicate their bearing.

In 1864 appeared the well known monograph on 'Mechanische Leistung, Wärmeentwickelung und Stoffumsatz bei der Muskelthätigkeit.' Helmholtz had shown that the tetanic contractions of a muscle, when continued for some minutes, are attended by a production of heat, but it re-

mained for Heidenhain to demonstrate a rise of temperature amounting to 0.003–0.005°C. with each individual contraction. He discovered the fact that the amount of heat evolved by a muscle in contraction increases with its tension; and in the demonstration that a muscle which contracts without doing external work gives off more heat than does the working muscle on contraction, the principle of the conservation of energy was illustrated by a significant experiment.

To the student of physiology the muscle studies briefly referred to may seem to bear little, if any, relation to Heidenhain's later investigations on the secretory processes in the organism. There was, however, a single great problem which gave the impetus to most of the physiologist's work. "I have endeavored all my life," he once remarked to the writer, "to learn something of the processes which go on in the living cells of the body. In my earlier studies I selected the muscle cells because of their large size. But I soon found that I could not reach the desired end by this means and accordingly I turned to the secreting glands, where I might better observe the entire cells under the microscope. Thus I have been carried farther and farther." Heidenhain's researches on the secretory processes have become classic, and his masterly volume on 'Absonderungsvorgänge' published in 1883 in Hermann's Handbuch der Physiologie will remain as a permanent contribution to physiological literature. The experimental researches which form the basis for these chapters, and in which Heidenhain enjoyed the assistance of a considerable number of co-workers in his laboratory, appeared in large part in the Studien aus dem physiolog. Institut zu Breslau, I.–IV., 1861–1868; in Pflüger's Archiv für Physiologie, and in Schultze's Archiv für Mikroskopische Anatomie.

The tendency of physiolological research at about the middle of the century had been in the direction of a distinctly mechanical theory of the secretory processes in which the physical forces resulting in filtration and diffusion were called upon to explain the known phenomena. The prevalent impression was in good measure due to the brilliant teachings of men like Brücke and Ludwig, although even the latter appreciated many of the difficulties which this aspect presented. It was left for Heidenhain to emphasize the inadequacy of any universal application of the current principles of physics and chemistry to satisfy the problems presented in the secretory functions. He insisted, first of all, on enquiring into the specific changes which take place in the individual organs incidental to their activity; and here again we discover the fundamental notion which was the key-note to Heidenhain's work, namely, the desire to investigate the ultimate seat of physiological changes, as he expressed it: "Das Wesen der lebenden Zelle die überall in ursprünglich einfacher oder differenzirter Gestalt die Vermittlerin und Trägerin des Geschehens ist."* In expanding these ideas Heidenhain has been occasionally misunstood, or unjustly accused of a belief in some 'vital' forces which transcend the possibilities of natural science. Indeed, I cannot refrain from referring to this fact, which always aroused regret in him; for to one who is familiar with his work nothing can seem more unjustified than this suspicion. No scientist of to-day will deny that the processes which go on in the living cells, that diffusion through a living membrane, is quite a different thing from the processes which can be provoked in these same elements after their death. This, however, does not imply the existence of other forces than the chemical and physical ones which continually manifest themselves in the inorganic world. It merely

*Hermann's Handbuch der Physiologie, V., 11.

indicates that our knowledge of how these forces are exerted and how the energy of the cell is transformed is hypothetical or wanting; and not until this deficiency is made up can the physiological experiment be interpreted in simple physico-chemical terms. This was Heidenhain's teaching.

The study of the secretion of the bile early claimed the attention of Heidenhain and his pupils. Besides contributing valuable data on the composition of this fluid and the conditions modifying its discharge from the liver, he made comparative measurements of the pressure under which the bile is secreted and the pressure in a branch of the superior mesenteric vein. In finding the bile pressure invariably twice as high as the blood pressure in the portal vein, he demonstrated for the bile, as Karl Ludwig had done in 1858 for the saliva, that secretion is not a mere act of filtration and thus a mechanical result of blood pressure.

The year 1866 marked the beginning of a series of papers which have contributed more than all others to bring renown to the Breslau physiologist and which mark a distinct advance in physiological knowledge. I refer to the brilliant researches on the salivary, gastric, pancreatic and other glands, in which physiological experiment was successfully combined with histological investigation. The facts discovered have been verified by numerous observers and are familiar to every biologist. Here was shown for the first time that in the secreting glands structural changes go on hand in hand with functional processes. With characteristic patience and thoroughness the various glands were made the subject of an exhaustive study and each new field afforded new problems and new results. For the salivary glands it was shown that the production of specific constituents and the secretion of water are more or less independent processes and thus the idea of distinct trophic and secretory nerves was introduced into physiology. For the pancreas, too, Heidenhain indicated indirectly the existence of specific secretory fibres, which Pawlow has since directly proved. The distinction between serous and mucous glands was also pointed out on the basis of structural, chemical and functional differences.

In his studies on gastric and pancreatic secretion Heidenhain pursued with success the plan which had been found valuable in the case of the salivary glands, and we owe our knowledge of the minute structure of these organs during rest and activity in large part to the labors of this investigator. The fundus and pyloric fistulæ are examples of the valuable methods of research developed by him. Almost simultaneously with Rollet he announced the distinction between the central and parietal gastric cells; his discovery, in 1875, of the so-called 'zymogen' of the proteolytic enzyme of the pancreas has been followed by announcements of precursors for other ferments and has added a new idea to the theory of secretion.

Contrary to the older theory of Bowman, Ludwig had taught that the urine is excreted entirely through the epithelium of the Malpighian capsule, the fluid being eliminated in consequence of purely mechanical filtration, and undergoing a subsequent concentration by the diffusion of water into the lymph spaces surrounding the kidney tubules. Heidenhain's experiments first demonstrated conclusively that the epithelial cells of these tubules take a prominent part in renal secretion. He did not fail to note, at the same time, the close dependence of secretory activity upon blood flow, *i. e.*, upon material for cellular work and upon the presence of oxygen; thus was emphasized the teleological significance of Claude Bernard's discovery that the blood vessels of secreting glands are greatly dilated during glandular activity.

The researches to which the later years of Heidenhain's life were devoted followed

in the course prepared for them by the earlier investigations. In several comprehensive and valuable papers on the histology and physiology of the intestine the inadequacy of osmotic forces to accomplish the work of absorption under many conditions is experimentally shown, the methods of the newer physical chemistry being drawn upon to yield results in a new field. Simple physical forces were supplemented by 'physiological' processes and the seat of these was assigned to the living epithelial cells. The researches on the formation of lymph which have appeared from the Breslau institute in recent years have opened up a broad field of inquiry that, together with the problems of absorption and transudation, is interesting physiologists to-day as perhaps few other themes are. Nowhere in Heidenhain's hypotheses have simple physical factors been excluded; but the difficulty or inadequacy of the latter in accounting for all the facts known is made apparent. And remembering the many differences of opinion that have arisen, let me quote the words of Professor Michael Foster: "In the controversy thus arisen, the last word has, perhaps, not yet been said, but whether we tend at present to side with Heidenhain, who has continued into the past thirteen years the brilliant labours which were, perhaps, the distinguishing features of physiological progress in preceding periods * * * or whether we are inclined to join those who hold different views, we may all agree in saying that we have, in 1897, distinctly clearer ideas of why secretion gathers in an alveolus or lymph in a lymph space than we had in 1884.'*

The preceding must suffice in this place to indicate some of the advances which physiology owes to Heidenhain. If to these is added the mention of his researches on the tonic contractions of sphincter muscles, on the heart and the nervous system, on hypnotism, etc., one cannot fail to be impressed by the broadness of the man. As a scientific writer his style is interesting and convincingly logical. His two monographs in defence of vivisection* have been widely circulated. As a teacher Heidenhain enjoyed unusual success. His lectures were remarkable for the lucid treatment of every department of physiology and histology, and few physiologists, I venture to add, were so liberal in their demonstrations. With every chapter at once made historical as well as critical, and giving evidence of a very wide acquaintance at first hands with the literature of the subject, these lectures would form an admirable text-book with which few of those now used on the Continent could favorably compare. The modest equipment of the old laboratory formed a striking contrast to the splendid results it yielded at the hands of a master.

Heidenhain's home life was charming and the reception within the family circle always cordial. To one associated with him in his work, nothing was more impressive than the man's intense devotion to his science. The indifferent student could expect little sympathy from Heidenhain; but no attention was spared, no effort too great in behalf of the individuals who won favor in the Breslau institute. Logical argument and unbiased observation characterized Heidenhain's presence in the laboratory. His thoughts continually wandered into the realm of unanswered problems, and more than once in recent years did he express the regret that the days still left must be brief, at most, for the tasks awaiting completion. These fruitful labors have, indeed, been ended too soon.

PHYSICS AT THE DETROIT MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SECTION B of the American Association for the Advancement of Science met with Professor Carl Barus in the chair and Professor Frederick Bedell as Secretary. 'Long Range Temperature and Pressure Variables in Physics' was the subject of Professor Barus's vice-presidential address, which has been published in full in SCIENCE. It was very interesting and was very well received. The address dealt with the historical development of pyrometry and piezometry, with a view to the present state of progress in these subjects, and with especial reference to their application to problems on the physics of the earth's crust.

The first paper on the list was by Professor F. P. Whitman and Miss Mary C. Noyes on the effect of heat on the elastic limit of copper wire. Their work was a continuation of a research on the effect of heat on Young's modulus (published in the *Physical Review*, Vol. II., p. 277). The yield-point was found to increase as the wires were stretched, heated and cooled. From a long series of tests made on the same wire it appeared that the wire was approaching a permanent condition. If the wire was heated to a red heat, or if it was stretched considerably beyond its elastic limit at the start, it maintained a nearly constant state afterwards. There were curves shown which graphically represented the changes in the behavior of the wire.

Professor A. L. Foley next read a paper on 'Arc Spectra.' He examined the light coming from the arc and found that it was due to concentric layers of different color. He used a concave grating to throw the spectra of different parts of the arc upon photographic plates. The outer layer was found to be strongest in the yellow. The upper carbon, whether positive or negative, was covered to a greater depth with the yellow flame. Inside the yellow was a blue area stronger at the positive carbon, and inside the blue and at the positive carbon violet was found.

Mr. Chas. F. Brush read a notable paper on the transmission of radiant heat by gases at varying pressures. Before describing his own investigations he referred briefly to those of Dulong and Petit, who used a large copper 'balloon,' about three decimeters in diameter, coated with lamp-black on the inside, in the center of which the thermometer bulb was placed. In discussing the cooling of bodies *in vacuo* Dulong and Petit fell into the grave error of deducing the behavior of the last few millimeters of gas from that of the rest. In this way they arrived at their 'Sixth Law:' The cooling power of a fluid diminishes in a geometrical progression when its tension itself diminishes in a geometrical progression. If the ratio of this second progression is 2, that of the first is 1.366 for air, etc. Mr. Brush said that his own observations show that this law can be approximately true only in the case of a large balloon, and at pressures from a few millimeters upward; that there is no suggestion of it where a small balloon is used, and at small pressures it does not obtain with either large or small balloons; he found that in a small balloon the cooling effect of the last millimeter of air is nearly ten times as great as that of all the rest, up to atmospheric pressure, combined. It was through misplaced confidence that Dulong and Petit were led to place a value on the rate of cooling *in vacuo*, something like a hundred per cent. too high; and as they derived the cooling values of gases by deducting the cooling effect of a vacuum from the total, all their values for gases are much too low. This error vitiates much of their other work. Mr. Brush carried his observations down to those made at one-twentieth of a millionth

of an atmosphere and found that the rate of cooling did not break down materially even then. To measure pressures he constructed two McLeod gauges. These gauges and their use Mr. Brush described in another paper on the measurements of small gaseous pressures. He gave, as an example of the delicacy with which small pressures were measured, the measurement of about two millionths of atmospheric pressure, with a probable error of only one part in three thousand of the quantity measured. From this he concluded that, with the apparatus described, small gaseous pressures might be easily measured with a probable error of less than a thousandth part of the millionth of an atmosphere. Mr. Brush showed many figures and curves to illustrate his work.

Professor W. A. Rogers read a paper on a final determination of the relative lengths of the imperial yard of Great Britain and the meter of the archives.

Professor Nichols read Mr. S. G. Barnett's paper on the influence of time and temperature upon the absolute rigidity of quartz fibres. Mr. Barnett found no time effect even after three months and an exceedingly small positive temperature coefficient of about three ten-millionths.

The discharge of electrified bodies by X-rays, by Dr. C. D. Child, was a subject which has been interesting scientific circles of late. The air, and in fact almost every gas, is an excellent insulator under ordinary conditions; but when acted upon by X-rays it becomes for the time a conductor. The resistance offered to the passage of electricity under these circumstances depends upon the pressure, temperature and kind of gas, as well as upon other more obscure causes. Dr. Child's paper deals especially with the influence of the *pressure* of the gas. He finds that, when the pressure of the air is increased from a few millimeters of mercury up to atmospheric pressure, the rate at which electricity can be conducted by the air in general increases to a maximum and then decreases again. The pressure at which the conductivity of the air is greatest depends upon the E. M. F. tending to send current through it. If the E. M. F. is high the pressure for maximum conductivity seems to be greatly in excess of atmospheric pressure and lies beyond the range of Dr. Child's measurements.

In addition to a careful study of the effect of pressure upon the phenomena, Dr. Child has also investigated several other points, some of which have heretofore been in dispute. For instance, he finds that electricity can be continuously discharged from a charged body under the influence of X-rays, even when the body is covered with a *solid* insulator, such as a thin layer of paraffin. This result agrees with the observations of Professor J. J. Thomson and contradicts in part the conclusions of Lord Kelvin. Dr. Child has also studied the effect of X-rays developed by an induction coil when the rate of interruption is varied. Many parts of Dr. Child's work which cannot even be referred to here will go far toward explaining the irregular and contradictory results which most observers in this line have heretofore obtained.

Professor F. P. Whitman described some investigations which he had made on the brightness of pigmented surfaces under various sources of illumination. The colors of the surfaces were ten in number, ranging through the spectrum. The flicker photometer was used for the comparisons, and some very interesting information was obtained.

Professor H. S. Carhart read a paper on the design, construction and test of a 1,250 watt transformer which had been made under his directions by two of his students. The core type was chosen instead of the shell, for reasons of convenience, as the iron for the core could be cut at the tinsmith's without a die. From the data obtained in

its test it appeared that the transformer agreed in resistance, regulation and efficiency almost exactly with the values computed in advance. The fall in E. M. F. between no load and full load was 2.3 per cent., and the efficiency at full load was 95.4 per cent. This paper is published in the *Electrical World* for September 18, 1897. Dr. Karl E. Guthe described some experiments on the electrolytic action of condensers. He used commercial condensers, and found polarization and recovery much as in an electrolytic cell. He showed several curves illustrating the results obtained. The graphical treatment of alternating currents in branch circuits in cases of variable frequency, by Professor H. T. Eddy, was a very full exposition of the subject. Many diagrams were shown, in which a whole series of assumptions as to the capacity and self-induction gave a corresponding series of curves. It would not be possible to give a proper notice of Professor Eddy's paper without reproducing many of his diagrams.

Professor Alexander Macfarlane read an instructive paper on simple non-alternating currents. Professor A. G. Greenhill, of Woolwich, England, exhibited stereoscopic views of spherical catanaries and gyroscopic curves which were very interesting. The mathematics of each curve were given on the back of the card on which the stereoscopic projections of the curve were drawn. Professor Ernest Merritt read Dr. L. A. Bauer's paper on the magnetic survey of Maryland.

Professors G. S. Moler and Frederick Bedell exhibited apparatus adapted to determining the frequency of an alternating current. The instruments here included are two in number. The first one, which has already been described by George S. Moler (*Physical Review*, March–April, 1897), consists of a small synchronous motor brought to speed by a crank handle connected with the motor by a suitable train of gears. The apparatus contains an electrically operated speed counter, so arranged that its reading gives the exact value of the frequency of the alternating current with which the synchronous motor is supplied. The whole apparatus does not weigh over nine pounds. The reading is correct to within .05 of an alternation. The second instrument consists of a sonometer or monochord. The alternating current flows through a piano wire mounted upon a sounding board. The wire passes between the poles of a permanent magnet. By means of a sliding bridge the period of the wire may be made equal to that of the alternating current. This is indicated by the vibration of the wire. A scale is arranged so that the position of the bridge indicates the frequency directly.

Dr. W. J. Humphreys gave an interesting account of some experiments on the effect of pressure on the wave-lengths of the lines of the emission spectra of the elements. He found a shift of the lines toward the red about proportional to the pressure and to the wave-length. The shift appeared to be independent of the temperature. Professor C. L. Norton described a new form of coal calorimeter. An abstract of his paper is in the *Electrical Engineer* of September 9, 1897. The coal is burned with oxygen inside the calorimeter in a platinum crucible, on a very thin dish of platinum perforated with a large number of holes near the edge. The lightness and good conducting power of the platinum crucible and plate assure their being at a high temperature during combustion, and to this is due the completeness of combustion. No trace of carbon monoxide and no indication of soot is to be found in the resulting gases. Professor E. B. Rosa read Dr. F. A. Laws' paper on a new form of harmonic analyzer. An electrodynamometer was used. A current sinusoidal in character, and of frequency vari-

able in multiples of the main current, was sent through the fixed coil, and the main current through the other coil. The deflection of the electro-dynamometer gave means of computing the magnitude and phase of the different components.

Very interesting papers were read by Dr. N. E. Dorsey, on the determination of surface tension of water and of certain aqueous solutions by the method of ripples; by Professor Frank E. Bigelow, on the series of international cloud observations made by the United States Weather Bureau; by Professor C. F. Marvin, on kites and their use by the Weather Bureau in the exploration of the upper air, and by Mr. B. B. Brackett, on the effects of tension and quality of the metal upon the changes in length produced in iron wire by magnetization.

Professors E. W. Morley and D. C. Miller presented a joint paper on the coefficient of expansion of certain gases. As the coefficient of expansion of hydrogen has been determined by the International Bureau of Weights and Measures at Paris, with a very high degree of precision, that of other gases may be determined by comparison. The method used in these experiments is a differential one, in which the difference in the expansion of oxygen and hydrogen, for example, can be determined with accuracy. Hydrogen is placed in one globe of five liters capacity and oxygen in a similar globe. These globes are connected to a manometer. They are first surrounded with melting ice, and then with steam. The differential expansions are readily observed. In this way the coefficients of expansion of four gases have so far been determined as follows:

Carbon Dioxide	0.0037122
Nitrogen	0.0036718
Air	0.0036719
Oxygen	0.0036729

A Note on the Construction of a Sensitive Radiometer was read by Professor Ernst Fox Nichols. In this paper the construction of a new form of compensating torsion radiometer, used recently in a number of researches in the remote infra-red spectrum, was described in detail. The instrument is capable of a higher degree of sensitiveness than either the spectro-bolometer or linear thermopile. A steadiness of action and freedom from extraneous disturbances, when working at high sensitiveness, are secured by means of the compensating action of two precisely equal vanes symmetrically mounted on either side of the axis of a quartz fibre suspension. The system, in consequence, is acted upon differentially by all accidental disturbances, while rays to be measured are concentrated upon one of the vanes. The degree of sensitiveness actually attained in one instance was so great that the influence of rays from a single candle at a distance of one-third of a mile could be detected and roughly measured. With an instrument of this kind Professors Rubens and Nichols have recently discovered heat waves one-fortieth millimeter in length, and have demonstrated their electro-magnetic character.

Professors E. L. Nichols and E. Merritt presented a paper on the photograph of manometric flames. The photographs were taken on a revolving drum of sensitized film, and showed in a striking way the effects of various sounds. Words and short phrases were spoken before the receiver. It was of interest to note that the effects of nearly like sounds could be distinguished in the photographs. The paper was illustrated with many lantern slides.

Professor Carl Barus read papers on the rate at which hot glass absorbs superheated water, and on a method of obtaining capillary canals of specified diameters. In the former he computed from experiment that there is an absorption per hour of 0.025 $\overline{\text{cm.}}^3$ of liquid water per $\overline{\text{cm.}}^2$ of glass sur-

face at 180°C. The importance of the observed increase in compressibility and in volume contraction in the lapse of time was especially dwelt upon. In the latter paper he said that elastic tubing punctured with 5,000 to 10,000 extremely small holes was subjected to external and internal pressure. The mean diameter of the pores in any given case is computed from the pressure-difference just necessary to cause a flow of gas against the capillary reaction of the wet porous septum. The author points out various applications of such tubes. Among other points, the cyclic character of the flows of liquid through the pores, when pressure increases and decreases consecutively, is exhibited.

Professor Frederick Bedell read a paper written by himself, Professor R. E. Chandler and Mr. R. H. Sherwood, Jr., on the predetermination of transformer regulation. To determine the regulation by this method a wattmeter, ammeter and voltmeter are located in the primary circuit. One set of readings is taken with the secondary short-circuited by a stout copper wire, the primary voltage being adjusted until the normal full-load current or any desired fraction of it flows in the transformer. No other data for obtaining a complete regulation curve is required except the one set of readings above mentioned and the magnetizing current. If a wattmeter reading is taken when the magnetizing current is measured, the data is sufficient to plot a complete efficiency curve as well as a curve for the regulation of the transformer. The two sets of measurements then consist of the reading of a wattmeter, voltmeter and ammeter, first on short-circuit with normal current, and second on open-circuit at normal voltage. The wattmeter reading in the first case gives the copper losses; in the second case, the core losses. It is commonly convenient to use the high-potential coil as primary in the short-circuit measurements, and the low-potential coil as primary in the open-circuit measurements. A high-potential supply is not then needed, and as no power is required except to supply the losses, the complete test of a transformer may be made with an incandescent lighting circuit for the source of supply, a 50 light transformer being tested from one 16 c. p. lamp socket. The total drop is found by laying off in the proper manner the inductive drop, the magnetic leakage drop and the drop due to ohmic resistance. The method is theoretically an almost exact one. Practically it is an exact method and less likely to error than the ordinary method of determining the regulation of a transformer by loading it. The results given in this paper (given in full in *The Electrical World*), from a long series of tests on seven transformers of various makes, shows the reliability of the method, the secondary voltage at full load determined by it varying usually less than one or two-tenths of a volt from the voltage as found by measurement on the transformer when actually loaded. An approximate method (by Kapp) used by one of our large electrical companies gives less accurate results. The reader is referred to the data given in the full paper.

An electrical thermostat, by Dr. W. R. Whitney, consisted of mercury in a U tube. One arm of the tube contained ether, and the other air, at reduced pressure. One platinum wire was fused into the bottom of the tube and another above the mercury in the leg of the tube containing the ether. On the rise of the temperature the ether gas expanded much more rapidly than the air and forced down the mercury below the ether; a control electrical circuit through the platinum wires and the mercury is thus broken, and through it the heating circuit. Professor W. O. Atwater and E. B. Rosa described their apparatus for testing the law of conservation of energy

in the human body. The subject was confined in a room whose walls consisted of a layer of copper, outside of which were one layer of zinc and three layers of wood, with air spaces between. The temperature of the air spaces was kept the same as that of the inclosed room, by means of currents of air. The condition of uniformity of temperature was tested by many thermo-electric junctions in series, which were distributed over the surface as uniformly as possible. The average position of the galvanometer mirror was kept zero. A deflection of one millimeter on the scale corresponded to one one-hundredth of a degree Centigrade. The amount of heat evolved in the room was calculated from the corresponding mass and change of temperature of the air which was forced to enter and leave the room through pipes. Frequent analyses of the air were made to determine carbon-dioxide and water vapor. The average of the results indicated that the law of conservation of energy was true.

Professor E. B. Rosa read a paper by himself and Mr. A. W. Smith, on electrical resonance and dielectric hysteresis. The dielectric experimented on was used in the form of a condenser, which was placed in an electric circuit, in series with a coil whose self-inductance was just sufficient to bring the alternating current used into phase with the E. M. F. The power expended in the circuit was made up of two parts, one proportional to the resistance of the coil, and the other proportional to the equivalent resistance of the condenser. These quantities multiplied by the square of the current (virtual) gave the power expended.

Dr. Margaret E. Maltby presented an interesting paper on a method for the determination of the period of electrical oscillations and some applications of the same, which was based upon a new application of the Wheatstone bridge principle. The two halves of the measuring instrument—an electrometer—serve as two arms of the bridge, and the other two contain a condenser joined to the electrometer needle and the two pairs of quadrants respectively. The relation that exists between these two, when there is no deflection, is a function of the rate of alternations in the current that passes through the system, viz: $T = \pi CR$, when T is the period of a single alternation, C the capacity and R the resistance. If C is known in electrostatic units and R in electromagnetic units, C/v^2 should be substituted for C above, and it is then possible to solve for v. Other applications of the method are evident. See Wiedemann's Annalen, B. 61, H. 3, S. 553.

In a joint session of Sections A and B Professor G. W. Patterson, Jr., read a paper on the electro-static capacity of a two-wire cable, in which he deduced the formula

$$C = \frac{0.01206\,K}{\log \dfrac{\sqrt{4RD + D^2} + D}{\sqrt{4RD + D^2} - D}},$$

when C is the capacity in microfarads per kilometer, K the dielectric constant of the medium, R the radius of each conductor and D the least distance between them. Common logarithms are used. Professor W. F. Durand explained an approximate method of treating differential equations, in which he integrated by summing up areas considered as trapezoids. By making the intervals small enough any degree of accuracy might be obtained. Professor Alexander Macfarlane explained a new method of solving certain differential equations that occur in mathematical physics. The method was applied to equations whose solutions involved exponential and sine functions. Mr. C. P. Steinmetz was on the program to read a paper on the screening effect of induced currents in solid magnetic bodies in an alternating field; but, much to

the regret of the Section, he was unable to be present.

GEORGE W. PATTERSON, JR.
UNIVERSITY OF MICHIGAN.

*A NEW METHOD OF SYNCHRONIZING STRATA.**

FOR nearly a century it has taxed stratigraphical geologists to the utmost to devise some rational and practical method by which the strata of the globe, the exposed sections of which are not visibly connected, can be brought into synchronous juxtaposition. Various schemes have from time to time been proposed, tried and abandoned. While it is a simple matter to correlate two rock outcrops which are not far away from each other, the difficulties rapidly increase with distance and by existing standards the determination of the exact equivalents finally become almost impossible.

It is the special province of geological correlation to establish a general chronologic sequence for rock successions more or less widely separated geographically. The main features of some of the more important standards of comparison that have been adopted or are being used may be briefly considered, their scope defined and their limitations noted. These methods fall into two main categories: (1) the strictly physical, and (2) the biological. Of these the latter have, for many years, been most widely followed. At the present time the former are beginning to assume much greater prominence than ever before.

So profound an influence have the organic remains entombed in the rocks had on correlation problems that it has only been very recently that the inherent weaknesses of this criterion has begun to be appreciated. The advantage of the physical method over the biological is indicated by the remark made lately by McGee that "Nearly as much information concerning the geological history of the Atlantic slope has been obtained from the topographic configuration of the region within two years as was gathered from the sediments of the coastal plain and their contained fossils in two generations."

Indeed, for more than a score of years that branch of geology called stratigraphy has been practically at a standstill. Its methods are the same that were used 50 to 75 years ago. However, the science of geology as a whole has made gigantic strides. Within the last two decades several entirely new branches have sprung into existence. New and refined methods of working have been formulated. With all this activity going on about it, stratigraphy itself has been at last provided with new weapons of offense and defence, and is beginning to experience a revival that is surely destined to restore its old time prestige.

The scope of the purely physical criteria of correlation and of geological classification as set forth in late years appears to have been generally overlooked. Attention needs to be called only to a few of these. Irving and Van Hise have formulated admirable methods of correlation, in which organic remains are left entirely out of consideration. McGee and his colleagues have, by purely physical methods, attacked the unfossiliferous deposits of the coastal plain and then have applied the same methods successfully to the fossiliferous terranes. Davis and others have rejuvenated the old methods of stratigraphical continuity and lithological similarity, by making possible a system of correlation by geographic forms, and broad areas are now being geologically mapped by this method alone. All of these methods are more or less complex and not simple, but they demonstrate that newer and more natural ways are rapidly replac-

* Abstracted from a paper read before the Academy of Sciences of St. Louis.

ing the older and more artificial ones, and that there is ample hope for devising physical means of correlation that are more in harmony with the real nature of the problems involved.

Still more recently it has been suggested that the real basis of geological correlation should be found in the causes giving rise to and governing sedimentation. This involves primarily a classification founded upon mountain-making movements. It is proposed, therefore, to emphasize this factor as fundamental in the marking off of the leading subdivisions of geological time, and to define general stratigraphical succession in accordance with the cycles of orogenic development, calling the classification or fundamental principle of correlation a systematic arrangement by mountains, or orotaxis. It is believed to overcome many of the difficulties that are usually encountered in correlation, in that it enables successions of strata to be paralleled not only in provinces whose geological history has been similar, but in those in which it has been very different.

Charles R. Keyes.

CURRENT NOTES ON PHYSIOGRAPHY.

THE ROCKY MOUNTAIN FRONT.

Monograph XXVII., U. S. G. S., on the Geology of the Denver Basin in Colorado, by Emmons, Eldredge and Cross, gives some account of physiographic features amid its detailed description of geological structures. The mountain front, when seen from a distance, rises as if from the sea in a continuous but rugged slope. A closer examination shows that, after reaching a certain height, the frontal spurs ascend more gradually to the main crest of the range, which lies unexpectedly far back. The upper valleys are wide open, but descend into deep and narrow gorges towards the 'shore line.' This is taken to indicate a revival of stream action by uplift, after an advanced stage of denudation had been reached when the region stood at a lower level. The hog-back ridge of the upturned foot-hill strata (Dakota), with the longitudinal subsequent valleys behind it, is generally even and continuous. Zigzag turns are formed on occasional folds; lapses of the ridge are noted at Golden and Boulder, where the Dakota sandstone was not deposited. The moderate relief of the Plains is shown to result from extensive denudation; the uppermost members of the series are broadly stripped off, leaving wide valleys between uplands and mesas of significant relief to the cross country traveller, but broadly plain in comparison to the bold mountain front.

CASTLE MOUNTAIN, MONTANA.

Castle Mountain is an outlying member of the Front range of the Rocky mountains in Montana, between the Missouri and Yellowstone rivers. It is described by Weed and Pirsson (Bull. 139, U. S. G. S.) as a 'dissected volcano,' although the considerable cone that must have once risen here (as attested by lava flows and tuffs) has been almost completely denuded, and the existing mountain of massive granite is hypothetically represented as of laccolitic structure in the corrugated beds of the heavy stratified series; the granites being older than the effusive materials. As is so generally the case in the Rocky mountains, moderate deformation occurred after extensive denudation of the corrugated strata, and considerable stratified deposits now mark the sites of lakes thus formed; the plains of Lake Smith, west of Castle Mountain, being the local illustration of this geographical element. The volcanic eruptions were antecedent to the lacustrine period, as the lake beds consist largely of stratified volcanic tuffs. Glacial action is indicated by well marked moraines which are referred to two epochs.

The description of the lake beds above mentioned suggests a recurrence to a note in a recent number of SCIENCE. The lower beds, 200 feet of well-indurated clays, are covered with sandstones and conglomerates, 'much cross-bedded and greatly resembling the Pliocene lake beds so common in the mountain valleys of Montana.' The upper beds range from marls to conglomerates, varying rapidly in kind and composition. Is it not probable that these variable upper beds are largely of fluviatile origin?

SCENERY OF YELLOWSTONE PARK.

'SOME geological causes of the scenery of Yellowstone National Park' are discussed by A. R. Crook (Amer. Geol. XX., 1897, 159–167), but with inadequate attention to the action of ordinary erosive processes. Mention is briefly made of the uplift of various mountains, but their extensive denudation into existing forms is hardly referred to, except under the head of glacial action, which is given an excessive value. The extreme youth of the Yellowstone Canyon in contrast to the maturely sculptured valleys of its headwaters, one of the most striking features of the Park, finds no mention. Although punctuated here and there by geyser basins and surrounded by a frame of bold mountains, the monotony of the scenery over large rhyolite areas will disappoint many visitors who read exclamatory descriptions of this 'Wonderland of America.' The bicycle as a means of travel in the Park deserves notice to intending visitors of the hardier kind.

THE PHLEGRÆAN FIELDS.

THE Oxford University Geographical Studentship, held in 1895–96 by R. T. Günther, leads to an essay under the above title as the result of extended field work (London Geogr. Journ., X., 1897, 412–435). The area studied lies west of Naples—a region of 'crater-like hills and hollows, volcanic ridges and trachytic rocks,' known as the *Campi flegræi*, or Burning fields. It is associated with level stretches of fertile volcanic soil, spread by water or other agency and known as the *Campagna felice*. Volcanic activity, as a cause of topographic features, has here been manifested in a slow outwelling of fluid materials, forming heaps or streams of lava; or in explosive discharges, forming craters surrounded by circular ringwalls of débris. The older volcanoes are much altered by stream and marine erosion, as well as by later volcanic action. Twenty-six craters more or less completely preserved are described and classified according to relative age. The later craters are smaller and nearer the shore than the older ones.

In view of the well-determined occurrence of calderas, as a result of destructive volcanic action in contrast to the constructive action that produces typical craters, it is to be regretted that no consideration is given to the differences between these two serviceable types of volcanic forms.

HARVARD UNIVERSITY.

CURRENT NOTES ON ANTHROPOLOGY.

THE PRESENT POSITION OF ETHNOGRAPHY.

THERE has lately been published, from the pen of Dr. Andrew Lincke, an interesting survey of the present position and recent contributions to the science of ethnography. Although his main attention is directed to the area of Germany, and particularly Saxony, he has also made an examination of what has lately been done for Asia and other parts of the world. His pamphlet of ninety-two pages is much more than a catalogue of books and papers. He undertakes to assign their respective value to those which he has himself read, and, although his notices are necessarily brief, they will be found useful indications to the reader and student. Dr. Lincke is himself well

known as a writer on folk-lore, and to this branch he devotes considerable attention in his essay. He does not concede much space to American writers or subjects, but for this omission the explanation in the preface relating to the difficulties of exhausting so wide a field is sufficient.

His paper, entitled 'Ueber den gegenwärtigen Stand der Volkskunde,' is published by the *Verein für Erdkunde,* in Dresden, and presumably may be obtained from it.

THE END OF THE HUMAN RACE.

ONE of his learned and thoughtful articles is contributed on this subject by the Marquis de Nadaillac in a recent number of the *Correspondant.* Making anew the calculation of the increase of population as compared with the increase of the food supply, he reaches the gloomy conclusion that in a few centuries there will inevitably be too little food to supply all the mouths. He compares the statistics of most civilized nations, and they appear to confirm his apprehensions. For instance, Russia alone, at its present rate of births, will in one hundred years be obliged to feed eight hundred million persons! What, he asks, can stem this overwhelming tide of population? He gives up the problem, and says that we must leave it to God, a solution which is more creditable to his piety than to his position as a scientist. The real solution is to educate men and women to the point where they will not recklessly produce offspring; nor yet ruthlessly prevent them, as is the case now in some departments of France, where the population is actually diminishing, although the wealth is above the average.

Unfortunately, modern prejudice stands in the way of a fair and full discussion of this solution.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

THE *Berichte* for September 27th contains a description by Emerich Szarvasy, of Budapest, of two new salts formed by the action of carbon dioxide and of sulfur dioxide on a solution of magnesium methylate. The first compound is a methyl-magnesium carbonate $(CH_3)_2Mg(CO_3)_2$ and may be looked upon as a methyl salt of magnesium bicarbonate, but unlike the latter, which decomposes on evaporating its solution, the methyl salt is comparatively stable, and its solution in methyl alcohol can be boiled without decomposition. If sulfur dioxid is used in the place of carbon dioxid the methyl magnesium sulfite is formed, which is also stable. The compounds may also be looked upon as magnesium salts of methyl-carbonic acid and methyl-sulfurous acid, and show the great resemblance in many respects existing between the carbonates and sulfites.

THE chemical world has great occasion to deplore the untimely end of Victor Meyer, and many lines of investigation begun by him, but not completed at the time of his death, will doubtless be for the present abandoned, while others may be carried on by his pupils and assistants, but will suffer for the lack of his guiding hand. One of his great works was the determination of vapor density at high temperatures, and while he had worked as high as 1,500°, and, perhaps, a little higher, he had entered upon investigations which would enable him to work above 2,000°. The most difficult part of the problem is to get a vessel to contain the gas, which will stand the temperature and at the same time be gas-tight. The first steps in this work are described in the last *Berichte.* The only material found which would satisfactorily withstand the heat of the furnace used, which was fired by a graphite burning in a stream of oxygen, was magnesia. This did not fuse, but when pure was very porous. A nat-

ural magnesia from the magnesite of Veitsch containing some ten per cent. of impurity, chiefly iron with silica, was found to sinter together in the heat of the graphite furnace and form gas-tight vessels. As the hottest zone of the furnace is very restricted, it was found possible to fire successfully only very small vessels in this manner. Attempts were made to fire larger density tubes in a oxyhydrogen furnace, but at the highest heat obtained the magnesia was still porous. Efforts to glaze the tubes also all resulted in failure. Here this exceedingly difficult investigation now stands, and it is to be hoped that Professor Meyer's assistant, Dr. Bodenstein, who, with Dr. von Recklinghausen, has carried it thus far, will go on with it to success. The value of density determinations at a high temperature is of great importance to chemical theory, and Victor Meyer's work has already afforded very valuable results, but if 500° more could be gained the value would be much increased.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE German Society of Men of Science and Physicians will hold its meeting next year at Dusseldorf, under the presidency of Professor Waldeyer, of Berlin. The secretaries of the meeting are Professor Mooren and Dr. von Viehoff, of Dusseldorf.

PROFESSOR A. A. MICHELSON, of the University of Chicago, has been made a member of the International Committee of Weights and Measures in the room of the late Dr. B. A. Gould.

WE called attention last week to the fifteenth Congress of the American Ornithologists' Union. The meetings at the American Museum of Natural History, for the presentation of scientific papers, beginning at 11 a. m. on Tuesday, November 9th, are open to the public and should prove of interest to many residents of New York. Information regarding the Congress can be had by addressing the Secretary, Mr. John H. Sage, Portland, Conn.

DR. FRIDJOF NANSEN arrived at New York on October 23d, and was in the evening the guest of the American Geographical Society, which conferred upon him the Cullum Geographical Medal and elected him an honorary member. Another reception was given to him on Monday night by the Swedish and Norwegian inhabitants of the city. A reception and dinner was offered him by the National Geographical Society, Washington, on October 26th. To-day the American Philosophical Society of Philadelphia will hold a special meeting, at which Dr. Nansen will present a paper on 'Some of the Scientific Results of Recent Arctic Explorations.' Dr. Nansen's first public lecture will be given at the Metropolitan Opera House, New York, on November 6th.

MR. E. E. HOWELL, of Washington, has just received from the U. S. Government Board of Control an order to construct a relief map of the Yellowstone National Park, for exhibition at the coming exposition at Omaha. This model, which will be 6 x 6½ feet in dimensions, will be based upon the surveys of the Park made by the U. S. Geological Survey and will represent the geology as well as the topography. The scale will be one inch to the mile, and there will be no vertical exaggeration. The map will be very accurate and complete, far surpassing the one made some years ago.

THE U. S. Geological Survey has practically completed the distribution of the Educational Series of Rocks, 175 suites of 156 specimens each having been sent out during the past summer to universities, colleges and technical institutions in the United States. There remains a small number of incomplete sets, which will be placed in such smaller colleges as will make them most useful. The Educational Series were prepared by the Survey with much care, for the purpose of aiding students in acquiring a general and special knowledge of rocks and promoting the study of geology.

THE first meeting of the new session of the Royal Geographical Society will be held on Monday, November 8th. After a short introductory address by the President, Sir Clements Markham, K. C. B., Mr. F. J. Jackson will give an account of the Jackson-Harmsworth expedi-

tion to Franz Josef Land, of which he was leader. At the second meeting Dr. Sven Hedin will describe the results of his four years' explorations in Central Asia. Lieutenant Peary has promised to go to England about the end of November, and it is to be hoped that he will appear before the Society early in December. Other papers which may be expected are by Sir W. Martin Conway, on his recent expedition to Spitzbergen; by Mr. E. A. Fitsgerald, on his explorations on and around Mount Aconcagua; Mr. Warington Smyth, on the Eastern Malay Provinces of Siam, and Dr. John Murray, F. R. S., on his recent investigations in the Scottish lakes. There will be a special meeting early in 1898 in connection with the 400th anniversary of the discovery of the Cape route to India by Vasco da Gama. Special afternoon meetings are being arranged for and Christmas lectures to young people. Under the auspices of the Society and the London University Extension a series of twenty-five educational lectures is being given in Gresham College by Mr. H. J. Mackinder, M.A., on the geography of Great Britain and the British seas.

THE principal medal of the Royal Photographic Society, London, has been awarded to Professor Gabriel Lippmann, Paris, for his work in color photography by the interference method.

WE regret to record the deaths of Dr. Justin Winsor, Librarian of Harvard University and President of the American Library Association, on October 21st, aged sixty-six years; of Professor John Foster, emeritus professor of natural philosophy in Union College, with the faculty of which he had been connected since 1836, aged eighty-three years; of Mr. E. P. Franz, formerly assistant to Professor Schaeffer at University College, London, in conjunction with whom he carried out important researches in neurology; and of Mr. William Scott, a well-known horticulturist and arboriculturist, director of the Royal Gardens and forests, Mauritius, at Stirling on the 3rd of October, aged thirty-eight years. He was home on leave after an unbroken residence in the tropics extending to sixteen years.

WE take from the *British Medical Journal* the following details regarding the late Professor Charles Smart Roy, whose death we were recently compelled to record. Born at Arbroath, Scotland, in 1854, he enjoyed a thorough education in training and research at St. Andrew's, in London and in Germany. Appointed George Henry Lewes student in 1880, he came to Cambridge and worked at the pathology of the heart, spleen and kidneys in Dr. Michael Foster's laboratory, where he gave a course of lectures on physiology to advanced students. On the election of Dr. Greenfield to the chair of general pathology in the University of Edinburgh, Dr. Roy was chosen to succeed him as Director of the Brown Institution. During the tenure of this office he visited the Argentine Republic for the purpose of investigating the causes of an epizoötic disease then raging among cattle in the Province of Entre Rios. He held the directorship for two years and a-half, when in 1884 he was elected to the newly-established professorship of pathology in the University of Cambridge. At first the teaching of pathology was carried on in rooms belonging to the Physiological Laboratory, but in 1889 the old chemical laboratory was transformed and refitted to accommodate the department of pathology. In this building, with the help of such able students as Griffiths, Hankin, Adami, Hunter, Wesbrook, Kanthack, Lorrain-Smith, Lloyd Jones, Cobbett and others, much brilliant work in pathology and bacteriology has been carried on under Professor Roy's direction. He invented many ingenious pieces of apparatus for physiological purposes, some of which, such as the oncometer and oncograph and the tonimeter, are universally known among investigators, and will continue to be called by his name. His researches on the heart, carried out with Professor Adami and independently, have thrown new light on that perplexing organ; it is, perhaps, on these that his reputation will chiefly rest.

A COMMITTEE has been appointed at the Johns Hopkins University to arrange and execute a memorial to Professor J. E. Humphrey and Dr. F. S. Conant, who died from pernicious malarial fever, contracted at Port Antonio, Jamaica, where they were conducting the Marine Laboratory of the Johns Hopkins University.

Dr. H. L. Clark, also of the expedition, nearly lost his life from the same disease.

The *Associazione Elletrotecnica Italiana* has appointed the following foreign committee to receive subscriptions to the fund which is being collected for the erection of a monument at Turin in memory of the late Galileo Ferraris: Rudolph Alioth, Professor E. Arnold, Dr. A. D'Arsonval, Professor W. E. Ayrton, Dr. Frederick Bedell, Otto T. Blàthy, Professor A. Blondel, C. S. Bradley, C. E. L. Brown, Professor Dr. Emil Budde, Dr. Coleman Sellers, M. Alfred Cornu, H. Cuénod, Max Déri, E. Desroziers, Dolivo Dobrowolsky, Dr. Louis Duncan, Thomas A. Edison, Edmunds Henry, Professor Jas. A. Ewing, Professor J. A. Fleming, Hippolyte Fontaine, Professor Geo. Forbes, Dr. O. Frölich, Professor Eric Gerard, Ernest Gerard, H. Görges, Eugen Hartmann, F. V. Hefner-Alteneck, Professor H. Hering, Dr. John Hopkinson, Professor Eduard Hospitalier, E. Hüber, J. Joubart, Gisbert Kapp, J. Kareis, Lord Kelvin, Professor Dr. Erasmus Kittler, Dr. Friedr. Kohlrausch, W. John Lieb, Jr., W. H. Lindley, Professor G. Lippmann, Dr. L. Lombardi, Professor E. Mascart, Senat. Montefiore, W. M. Mordey, Alois Naville, Professor Oliver Lodge, Dr. A. Palaz, R. V. Picou, W. H. Preece, Pantaleoni, Emil Rathenau, C. W. Rechniewski, Professor E. Rousseau, Professor Henry Rowland, Alexander Siemens, Dr. A. Slaby, Charles P. Steinmetz, Dr. Gotthold Stern, Professor G. Peter Tait, Nikola Tesla, Professor Elihu Thomson, Professor J. J. Thomson, Professor Sylvanus P. Thompson, Rene Thury, Th. Turettini, Friedrich Uppenborn, Dr. A. von Waltenhofen, Dr. H. F. Weber, Edward Weston, Joseph Wetzler, Dr. V. Wietlisbach, Professor W. Wyssling, Professor Carl Zipernowsky. The American Association for the Advancement of Science, at the Detroit meeting, authorized Dr. Frederick Bedell to collect subscriptions from the members of the Association.

The Indian government has asked for twelve medical men to be sent out from England to the Bombay Presidency for duty in the plague-stricken districts.

The Linnæan Society of New South Wales, Sydney, desire applications for the position of Macleary bacteriologist, the salary of which is about $2,000 per annum.

The late Edward C. R. Walker has bequeathed $20,000 to the Massachusetts Horticultural Society, to be known as the Samuel Walker Fund. The bequest is subject to several life interests.

The Staff of the North Carolina Agricultural Experiment Station has been reorganized as follows: Alex. Q. Holladay, Chairman of Council; W. A. Withers, Chemist and Acting Director; Frank E. Emery, Agriculturist; W. F. Massey, Horticulturist, Botanist and Entomologist; F. E. Hege, Poultry Manager; B. S. Skinner, Superintendent of Farm; A. Rhodes and C. W. Hyans, Assistants in Horticulture, Botany and Entomology; J. A. Bizzell, C. B. Williams, H. K. Miller, C. D. Harris, A. W. Blair, J. D. Hufham, Jr., and F. G. Kelley, Assistants in Chemistry.

At a recent meeting of the New York Zoological Society the executive committee reported that the plans for the zoological park are practically complete, and that it is imperative that the remainder of the first $100,000 of the building fund should be subscribed at once in order that the plans may be submitted to the Park Board without delay. If the needed sum is subscribed the completed plans will be laid before the Park Board at its meeting on November 1st.

Professor Lester F. Ward gave, last week, a course of six lectures at the University of Chicago, his subject being 'The Evolution of the Plant World as shown by Paleobotany.'

The Secretary of Agriculture will, on November 17th, deliver an address at the opening of the new building devoted to agriculture at the Tuskegee Normal and Industrial Institute for Negroes.

North Dakota Agricultural College and Station have in course of construction a wing for a new chemical laboratory. The laboratory, when completed, will cost $20,000.

The Journal of the Boston Society of the Medical Sciences will be enlarged to octavo size in October. By general consent of the Heads of

Departments it will contain full abstracts of experimental work carried on in the following institutions: the Medical School of Harvard University, the Experimental Laboratories of the Massachusetts General and the Boston City Hospitals, the Physiological and Biological Departments of the Massachusetts Institute of Technology, and Clark University. The numbers of the Journal will be issued promptly after each meeting of the Society, furnishing a very rapid means of communication of the results of investigation. There will be published at least ten numbers a year—running from October to June. The subscription price will be $2.00 a year.

MESSRS. HENRY YOUNG & SONS, Liverpool, announce the publication of the 'Bulletin of the Liverpool Museums,' issued by authority of the City Council. It will be edited by Professor H. O. Forbes, Director of the Museums.

MESSRS. G. P. PUTNAM'S SONS have, in course of publication, in cooperation with Messrs. Bliss, Sands & Co., of London, a series of scientific hand-books to be issued under the title of 'The Progressive Science Series.' The general editorial supervision of the series will be in the hands of Mr. F. E. Beddard, M.A. (Oxon), F.R.S. Each volume will be complete in itself and will be devoted to one distinctive subject. It is not proposed to consider the series from the purely technical side of the various sciences, but social and economic questions will be considered from their scientific aspect. In each treatise it will be the endeavor of the author to present not merely a study of his subject in its present status, but also to indicate the probable lines of future investigations. The publishers promise that the volumes will be fully illustrated, in so far as the subject matter calls for illustrations, and will be suitably and attractively printed and bound. Among the earlier volumes that have been arranged for are:

'The Earth's Structure,' by Professor Geikie.

'Volcanoes,' by Professor Bonney.

'The Science of Ethics,' by M. Berthelot.

'The Cell and Cellular Reproduction,' by Professor Hertwig.

'The Animal Ovum,' by the editor, Professor Beddard.

THE Royal Society of Victoria has issued the ninth volume of the new series of its proceedings, containing papers read before the Society during 1896. These are seventeen in number, including several valuable contributions to the natural history, geology and anthropology of Victoria.

THE *International Journal of Microscopy and Natural Science*, edited since its foundation, sixteen years ago, by Mr. Alfred Allen, and published by Messrs. Bailliere, Tindall & Cox, London, has been discontinued with the present issue. The editor explains that this is due to the sales not being sufficient to pay the printer's bills, but that the Postal Microscopical Society, with which the *Journal* was connected, will be continued.

THE University of the State of New York, following the plan it has adopted of lending to the schools libraries and pictures, offers to make loans of specimens of natural history from the State collections.

AT the recent meeting of the Medical Association of Central New York papers were presented on expert testimony in medico-legal cases, and a committee reported in favor of a change of the statutes, requiring all medical testimony to be brought in by a commission appointed to examine the subject, the medical experts being appointed by the Court as referees, and being paid by the county, not being allowed to receive fees from either the defense or the prosecution.

AT the opening meeting of the Royal Photographic Society, London, the President, the Earl of Crawford, made his annual address, his subject being 'Weights and Measures as they are used in Photography.' He spoke especially of the importance of using the metric system in photography, and urged makers to use the metric dimensions in their cameras, plateholders, etc.

THE London *Times* reports that the experiments in wireless telegraphy which are being made near Dover by the Post Office authorities are being continued, and have reached an interesting stage. They are continued daily with varying results, according to atmospheric con-

ditions. Mr. Preece, the Chief of the Telegraph Department, although he does not personally conduct the experiments, goes down occasionally to witness them and compare results, and advise as to future operations. The authorities are endeavoring to obtain as satisfactory results as those achieved by Marconi, but up to the present time they do not appear to have been so successful. The receiving apparatus is sent out every morning on a trolley, so that it can be transferred to different parts of the country to be experimented with. Strict secrecy is maintained in regard to the instruments, and when the experiments are concluded at the end of the day the apparatus is brought back to Fort Burgoyne and carefully guarded. The experiments are now being made within a radius of three miles of the Fort. Hitherto they have been confined to two miles with the most successful results, messages being freely and distinctly transmitted. At the three miles' radius, it is stated, the results are not nearly so satisfactory. In order to transmit to a greater distance the height of the vertical wire has to be increased. As the pole at Fort Burgoyne is already a considerable height, the use of the flying kite has been resorted to in order to test at still greater heights. The kite is composed of thin copper, a wire running from the tail to the transmitter.

IT is said that Dr. Alexander Edington, Bacteriologist to the Cape of Good Hope government, has found that the blood of animals affected by rinderpest, when treated with citric acid and kept for such a time as to ensure the death of the contagium, will, when injected, immunize all animals exposed to infection. Dr. Edington has practiced his protective injection on several large herds, and always with satisfactory results, the largest mortality having been a little over 3 per cent., or eight animals in a herd of 234.

IT is stated in *Natural Science* that the trustees of the Albany Museum, Grahamston, have decided to erect a new and more commodious building. The necessary funds are already in hand, and the work is to be proceeded with at once. The plans have been prepared by Mr. Viesebosse, architect of the Cape Town Museum. The new museum will be a two-storied building, 150 feet long by about 60 feet deep.

WE learn from *Garden and Forest* that the lumbermen now controling a large block of Big Tree forest, on the western slope of the Sierra Nevada, in California, are making a determined effort to obtain from Congress authority to cut the Sequoia timber in the General Grant National Park. This particular portion of the Sierra Reservation includes about fifteen hundred acres, and is covered with an exceptionally fine growth of Sesquoias and Sugar Pines, probably the oldest living organisms on the face of the globe. As *Garden and Forest* says, every individual is a monument which should be sacredly preserved for the benefit of future generations. To cut down one of these trees is a crime, and it should be a matter of national humiliation that a considerable part of the Sequoia forest has been allowed to pass from government control into the hands of lumbermen. There was no excuse for this; there would be less excuse in allowing those portions of the Sierra forest which have already been reserved for the benefit of the people to be opened to entry. The lumber, even, is not needed by the community, which can be abundantly supplied from the Redwood forests, and no one but a little group of men who expect to make money by this transaction has any interest in the success of the movement.

THE usual annual compilation of statistics relating to mines and quarries in the United Kingdom in 1896 has been issued by the Home Office and is abstracted in the London *Times*. The sources from which minerals are obtained in the United Kingdom are classed under five heads: (1) Mines under the Coal Mines Regulation Act; (2) mines under the Metalliferous Mines Regulation Act; (3) quarries more than 20 feet deep, which are now under the Quarries Act; (4) quarries les than 20 feet deep, which are not under the Quarries Act; (5) brineworks. Except in the case of iron ore and a few less important substances, the present volume contains no account of minerals raised from the quarries less than 20 feet deep. It is true that the amounts of clay, brick-earth, sand and gravel so obtained must be large; but without

further statutory powers no accurate account of the quantity and value can be given. Thanks to the courtesy of the owners, who have furnished returns voluntarily, accurate statistics of the output of the shallow ironstone quarries of the Midlands have been secured; and in like manner the output of salt from brineworks has been calculated. The exports and imports of each of the principal minerals, furnished by the Board of Customs, are given after the tables of production, and in several cases information as to distribution, supplied by railway and navigation companies, is added. Lists of smelters of the principal metallic ores follow the export and import tables, and in the case of iron the quantity of ore and coal used in the blast furnaces, and the make of pig iron, have been ascertained from voluntary returns furnished to the Home Office by the owners. The volume includes a table of the mines inspection districts, with the names and addresses of the inspectors of mines, assistant inspectors, secretaries to boards for examinations, and the Clerk of Mineral Statistics. The return also supplies a general summary of the value of minerals obtained from the colonies. The figures for 1895 were: Africa and Mediterranean, £5,506,739; Asia, £5,874,144; Australasia, £13,919,068; Europe, £139,289; North America, £3,842,586; South America, £446,695; and British West India Islands, £101,550; total, £29,830,071, as compared with £28,765,009 in 1894.

UNIVERSITY AND EDUCATIONAL NEWS.

PROFESSOR JAMES M. CRAFTS has been elected President of the Massachusetts Institute of Technology. Professor Crafts holds the chair of organic chemistry in the Institute and has been the acting president since the death of General Walker.

AT Cambridge University Mr. J. B. Peace, M.A., Fellow of Emmanuel College, has been appointed demonstrator in mechanism and applied mechanics for five years, and Mr. H. Higgins, M.A., of King's College, has been reappointed demonstrator of anatomy for five years.

DR. MOLLIER, of Göttingen, has been appointed professor of mechanical engineering in the Technological Institute at Dresden

THE New York City Board of Superintendents hold an examination for principalships of grammar schools on November 3d, 5th and 8th, which are open to candidates from any part of the United States having an experience of ten years in teaching. The salaries are from $2,500 to $3,500 per annum.

DISCUSSION AND CORRESPONDENCE.

LEWIS ON THE DIAMOND.

IN two papers* recently published Mr. George F. Kunz has reviewed 'Papers and notes on the genesis and matrix of the diamond by the late Henry Carvill Lewis.' In each he attributes to Lewis the theory that South African diamonds have resulted from the intrusion of igneous rocks into and through carbonaceous shales, and the crystallization of the carbon throughout the rock as it cooled, from hydrocarbons distilled from the shale that had been broken through. In his communication to SCIENCE, however, Mr. Kunz admits that in these papers Lewis does not distinctly assert that the shales are the origin of the carbon. Mr. Kunz derives his authority for his representations on this point from conversations with Lewis ten years or more ago.

It seems to me that Mr. Kunz does Lewis a serious injustice. Had the latter wished to commit himself in print to this theory it would have been easy for him to express himself in terms as positive as those which Mr. Kunz employs. Far from doing so he appears to support a radically different theory, viz., that the diamonds are phenocrysts and an integral part of the lava. In the following paragraphs I shall quote every phrase in these two papers which bears on the subject, the rest of the text consisting of lithological discussions and the like.

In his first paper, page 6, Lewis properly attributed the hypothesis of the derivation of the carbon from the shales to Mr. E. J. Dunn.† Lewis expresses no assent to this hypothesis, at least in this connection, and merely comments:

* Production of Precious Stones in the United States, U. S. Geol. Survey, Mineral Resources, 1896; and this JOURNAL, Sept. 17, 1897.

† Quar. Jour. Geol. Soc., Vol. 37, 1881, p. 610.

"If so, the atmosphere would be the original source of the diamond." A little later he remarks:

"The earlier theories as to the origin of the diamond have, in the light of new facts, quite given way to the theory that the diamonds belong to and are a part of the matrix in which they lie, and that this matrix is in some way of volcanic origin, either in the form of mud or ashes or lava." On page 8, however, he says:

"The rock occurs in two types, one not bearing diamonds, the other diamantiferous, and the distinction between them is suggestive. Both occur in the same mine, and are dark, compact, heavy rocks, closely resembling one another, and differing mainly in the fact that one is free from enclosures of foreign substance, while the other is full of fragments of shale and other impurities. It is the latter which is diamantiferous." What is suggested by the difference between these rocks Lewis does not further indicate. He was mistaken as to the facts, as he afterwards appears to have learned.

In his second paper, read in 1887, Lewis, in describing the mode of occurrence of the diamonds, remarks:

"It is interesting also to find that they become more abundant the deeper they are from the surface, and where also the volcanic action was more intense. * * * * * Carbonados and black diamonds are also common, not only in large crystals, but very abundantly as minute, almost microscopic, crystals. The abundance of these minute crystals is another proof that they are not enclosures brought up from some other matrix." He sums up the evidence as to the origin of the diamonds as follows:

"The explorations of the last few years have placed it beyond question that the serpentine rock, called 'blue ground,' is in reality the matrix of the diamond. For a time it was thought that the diamonds were washed into 'kopjes' from above, being mere alluvial deposits, as held by Mr. Cooper and others; afterwards, and until the present time, the idea has been general that they were carried up from below along with other inclusions, and that their true matrix was some gneiss or itacolumite, far below, from which they had become detached by volcanic agency. Others again, such as Döll, hold that, while the serpentinous rock is the matrix of the diamond, the latter is a secondary mineral due to the decomposition of the rock. But recent investigations seem to place it beyond question that diamonds are as much a part of the Kimberley rock as biotite, garnet, titanic and chromic iron and perovskite, and that, like these minerals, they may be considered as a rock ingredient. The fact that they continue just as abundant, if not more so, the deeper the mines are explored: that they are never found in, or especially associated with, the foreign inclusions of gneiss, granite or sandstone: that they are distributed abundantly through all parts of the rock: and that in each of the four principal mines the diamonds have distinctive features of color, lustre and shape, are, with the microscopical evidence of the eruptive character of the rock, strong reasons for holding that the diamonds now lie in their original matrix." This passage will bear but one interpretation and seems to represent Lewis's final opinion.

Later he refers to the fact discovered by Sir Henry Roscoe that the 'blue ground' contains a soluble hydrocarbon, but confines himself to characterizing this as a most interesting chemical observation. Lewis also presents Chaper's results, according to which the rock of the Kimberley mines results from a series of eruptions, between each of which there was time for the volcanic mass to consolidate, and in some of the mines it is possible to make out a chronology of the various eruptions.

The only other passages pertinent in this connection are those referring to the occurrence of fractured diamonds. The fact that fragments of crystals are often found in the mine he explains as due to the bursting of the diamonds on exposure to the atmosphere. He also notes, however, that many of the other porphyritic crystals of the kimberlite are broken.

Whatever Lewis may have said in conversation, his deliberately recorded opinion is that the diamond is a rock ingredient, as much a part of the rock as the garnet or the biotite. It cannot have been his wish to be represented as holding an opinion which, in these papers at least, he nowhere expressed, and from which he withheld his assent.

Lewis never visited Kimberley. I have done so, and from field observations reached the same conclusion as he did from the study of collections. Unfortunately my collection disappeared in transit, but a few notes may tend to throw a little additional light on the subject of the genesis of the diamond.

The De Beers mine and the Kimberley mine are each extensively developed, the former to 1,200 feet and the latter to 1,600 feet. As is well known, the mines are in volcanic necks. I gathered some evidence that these necks are not drilled through the rocks, but are local enlargements of persistent fissures. The adjacent rocks are in a nearly horizontal position and include quartzites, shales, sheets of melaphyre and of basalt. The quartzites are also cut by dikes of basic eruptives. The only bituminous rock in the district is the black shale, which is about 180 feet thick at the De Beers and 250 feet at the Kimberley. At each mine the under surface of this shale is only at the very moderate depth of about 350 feet from grass. In the upper part of the mines the kimberlite carried very numerous fragments of the shale. Below the shale stratum, however, the shale horses or 'floating reef' diminished in number very greatly, so that at over a thousand feet of depth only occasional fragments of shale are to be found. Those which I saw seemed totally unaltered. The edges of the fragments were sharp and there was no macroscopical evidence of any loss of carbon. Much of the lava is brecciated, but much also is solid with gradations between the two varieties. There is one well marked dike in the De Beers. It is known as the Snake, from its meandering course. It was determined by Stelzner as pikrite porphyry and as substantially the same rock as the blue ground itself. The 'Snake,' however, contains no diamonds.

The diamonds are distributed throughout the necks, excepting that they never occur either in horses (whether of shale or of other rock) or in the snake dike. They are found in what appears to be massive lava as well as in the breccia, but there are portions of the mass which are too poor in diamonds to pay for extraction. The diamonds are not grouped about, or especially associated with, extraneous fragments. On the other hand, they are curiously grouped in vertical pipes within the necks. The existence of these pipes was pointed out by Mr. M. Chaper and they were discussed by Mr. A. Moule. The diamonds from the several pipes seem to differ not only in abundance, but also in tint or physical character, so that with care a discrimination is possible. The pipes apparently represent successive eruptions.

It is important to note that the contents of blue ground in diamonds remains very nearly constant at different levels. The De Beers mine is now some 850 feet below the bottom of the shale, the Kimberley about 1,250 feet, and the walls of the necks or of the deposits contain no sensible amount of carbon over these intervals of depth, yet the average number of carats per 'load' of 16 cubic feet (about 1,600 pounds) does not vary to an important extent. The yield per load for the year ending June 30, 1896 (viz., 0.91), was almost exactly the same as for the year ending June 30, 1892 (viz., 0.92). In 1893 it was somewhat higher, in 1894 and 1895 somewhat lower. Now, to imagine that the carbon has come from the shale and permeated the lava downwards, in opposition to the flow of melted rock, to such depths as 1,000 feet, without great diminution of quantity, is almost impossible. One can, indeed, fancy still more deeply seated shale beds, but for this hypothesis there is no evidence at all.

While the diamond appears to be an original constituent of the kimberlite and occurs in South Africa in this manner at many localities, it may be classed as accessory, rather than an essential mineral, if there is any real distinction between these groups. Some of the rock is rich, some too poor to be worked, and some seems to be absolutely barren in diamonds. So also there are basaltic rocks poor in olivine and passing over into varieties substantially barren so far as this mineral is concerned. Similarly granites are sometimes rich in zircon and sometimes poor. Even so-called essential constituents, such as the quartz of granite, likewise vary in quantity, as, for example, when a granite passes over a syenite.

Lewis seems to have confounded two phenomena in discussing fractured diamonds. There are diamonds usually of a brownish tint which, after being exposed to the air for some

time, disintegrate. There are also diamonds of all colors and qualities which are found in the mines in a broken state. These are not cases of fracture in mining, whether by the use of explosives or otherwise. The fragments are embedded in the matrix and the crytals have been broken before final consolidation of the lava took place. They seem precisely analogous to the broken phenocrysts of hornblende or feldspar not infrequently found in lavas and such as Lewis found in kimberlite; it is asserted that in a solitary case two complementary portions of a single diamond have been found, one of them coming from a depth of two hundred feet greater than the other.*

Mr. Kunz inclines to ascribe the fracturing of diamonds to the brecciation of the lava. If this were the correct explanation one would expect to find the diamond fragments only at the surfaces of rock fragments, and to hear of complementary portions of diamond crystals found near together. The few specimens of still embedded fragments which I had an opportunity of inspecting did not bear out the theory of brecciation fracture, and I have noted above the only instance I could learn of in which complementary fragments have been discovered. It seems to me more probable that the diamonds and other fractured phenocrysts in massive lavas have been broken at the moment of explosive ejection from the volcanic melting-hearth.

I am not in a position to discuss Sir Henry Roscoe's discovery of a soluble hydrocarbon in the blue, for I do not know whether the massive lava free from shale, in the deeper workings, does or does not contain it. If it does, the origin of this substance would probably be most easily explained as similar to that of the crystallized carbon, and as due to some such process as that to which Mr. Mendeleeff ascribes the formation of the Baku petroleum, the decomposition of carboniferous, terrestrial, metallic iron.

In closing this criticism it is appropriate to quote the opinion of Mr. Gardner F. Williams,† a mining engineer who for many years has managed the De Beers consolidated mines with conspicuous ability. "The proofs are most conclusive that the diamonds were not formed *in situ*, but have come up from below with the blue ground."

GEORGE F. BECKER.

WASHINGTON, D. C., October, 1897.

*E. J. Loomis, Eclipse party in South Africa, 1896, p. 121.

† Second annual report of the De Beers consolidated mines for the year ending March 31, 1890. In this report Mr. Williams quotes Stelzner as having determined the 'snake dike' as pikrite porphyry and the blue ground as essentially the same rock. The melaphyre sheet underlying the bituminous shale Stelzner considered as olivine diabase. Mr. Williams probably took these determinations from letters, for I can find no publication by Stelzner on the subject until 1893 (Isis Society, Dresden). In this paper Stelzner adopted Lewis' term 'kimberlite' for the blue ground. He assented to Knop's view, that the kimberlite magma was itself carboniferous or hydrocarboniferous and that the diamond crystallized out as a primitive rock constituent. He mentioned, as of special bearing on this subject, a specimen presented by Mr. Williams to the Freiberg Museum, a fragment of diamond which is intergrown with pyrope and is thus presumably from the same habitat as this essential element of the kimberlite.

NOTE ON 'THE EASTERNMOST VOLCANOES OF THE UNITED STATES.'

IN a letter published in SCIENCE (Vol. VI., No. 146, pp. 594–595, October 15, 1897) Mr. Robert T. Hill tries to correct the map showing the distribution of volcanoes in the United States, plate 5, published in 'Professor I. C. Russell's magnificent volume on the *Volcanoes of North America*.' He says the "conclusions on the part of Professor Russell are erroneous and mar his otherwise excellent work, for some of the most beautiful and perfect volcanic craters in the United States occur in New Mexico." Consequently Mr. Hill gives a sketch of the New Mexican region, giving 'supplementary data concerning the distribution of volcanic phenomena.' Among the omissions of the true craters of New Mexico, which have escaped Mr. Russell's notice, the groups of volcanic cones and craters with flows of lava, called the Cerrito, lying between Galisteo and the Rio Grande are quoted in the letter, but erroneously marked in the accompanying sketch as forming a line of three black discs or craters at the western

foot of that part of the Cordilleran mountain series called Sierra de Sandia and bordering exactly the Rio Grande del Norte; just where is situated the town of Albuquerque and the villages of Alameda, Sandia and Bernalillo.

Such erroneous volcanic geography has never been given in a map of the United States even on the most rough sketch.

The group of craters of the Cerrito was first discovered by the present writer in 1853, and recorded as such, on the geological map of New Mexico, 1857, published in Zurich, Switzerland, in *Geology of North America.* They occupy a part of the mesa existing between the southern system of the Cordillera called the Santa Fé Mountains and the northern end of the Sierra de Sandia, nearer to the city of Santa Fé than of Albuquerque, and close to the railroad station called Lamy. The Cerrito lie between Galisteo, Cieneguilla and Lamy. On the sketch map of Mr. Hill, the crater of the old volcano called Cerrito ought to be placed just near the head waters of the Rio Pecos, a little south of the Santa Fé Mountains and northeast of the Sierra de Sandia; and the three black discs of Albuquerque, Sandia and Bernalillo, on the eastern side of the Rio Grande, scratched out.

JULES MARCOU.

GLACIAL STRIÆ.

TO THE EDITOR OF SCIENCE: While strolling over the low hills adjacent to the Delaware river in Northampton county, Pa., I found unmistakable glacial striæ, at least four miles south of the front of the terminal moraine, as commonly defined.

Three parallel scratches, with traces of a fourth, on the sloping side of a shelf of limestone that had just been uncovered from under what seemed a slight bed of true till, and with a direction S. 20 W., made a mistake of judgment, it seems to me, impossible. The repeated occurrence of such ice traces throughout this county to a distance of at least twenty miles south of the moraine most certainly opens for investigation the question of the southern limit of glacial ice.

Yours,

ALBERT G. RAU.

BETHLEHEM, September 15, 1897.

THE ALLEGED EXTINCTION OF LINES OF DESCENT.

PROFESSOR W. K. BROOKS contributed to this JOURNAL some time since (February 1, 1895) an interesting article entitled 'An Inherent Error in the Views of Galton and Weismann on Variation.' The argument of this paper was based on the alleged necessary extinction of lines of descent. Thus Professor Brooks writes:

"Of all the individuals of a species which lived at a given period, very few would have descendants at a later period." "Most of the individuals in each generation must fail to perpetuate their lines to remote descendants." "If a city like Baltimore, where the strangers to each one of us outnumber our acquaintances a thousand fold, could be quarantined against people from outside for a thousand years, each generation would be like the present one so far as known relations are concerned, although at the end of the period the inhabitants would certainly not be descended from the Baltimorians of our day, but from only a very few of them. Most of our lines would be extinct."

I return to the subject because Professor Brooks' statements carry great weight in a subject important for theories of heredity and evolution, and it seems to me that they contain 'an inherent error.' Family names will become extinct, as shown by Mr. Galton, but not lines of descent that have persisted for several generations. If the present population of Baltimore is to remain stationary, some of the inhabitants having no offspring, the others must on the average have more than two. If, for example, we simplify the problem by supposing one-half of the population to be sterile, and each of those who are fertile to have four offspring who survive to maturity, then only one-sixteenth of the fertile parents would have no descendants in the third generation. Of the balance only one line in 256 would become extinct in the fourth generation, one in 65,536 in the fifth, and one in 4,294,967,296 in the sixth. With families of variable size, etc., the calculations would become intolerably complex; but in any population not decreasing in numbers the descendants of each individual tend to increase in a geometrical ratio and cannot become extinct after several generations. If King Alfred and King Alfred's barber had lines of descent lasting several generations, we are each

descended from both of them; or, if not, our descendants (should we have them) will be.

Genealogies are not, as Professor Brooks states, 'represented by a slender thread of very few strands,' but by the branching tree to which he objects, except that there are many trees whose branches interlace and anastomose.

COLUMBIA UNIVERSITY.

SCIENTIFIC LITERATURE.

RECENT BOOKS ON PHYSICS.

Modes of Motion. By A. E. DOLBEAR. Boston, Mass., Lee & Shepard. 12mo. 120 pp.

The second title of Professor Dolbear's little book is 'Mechanical Conceptions of Physical Phenomena.' It is essentially a popular presentation of the fundamental properties of matter as contrasted with those which the author assumes the ether to possess. Matter is contrasted with ether in reference to a series of twenty-two of its commonly recognized attributes, in none of which are the two found identical, and in the great majority of cases they are declared to be directly opposed to each other. Indeed the author makes special effort to demonstrate the absolute dissimilarity of matter and ether, and in so doing even goes so far as to declare that the latter in no way affects the senses. But he evidently believes in the possibility of transforming ether into matter and matter into ether and the indestructibility of matter or the impossibility of transmitting the elements he regards as tentative assumptions. A few sentences are devoted to a consideration of the origin of the ether itself, but the author finds quick refuge in the easy 'assumption that it was in some way and at some time created,' this being, he declares, more rational than to assume that it always existed. The book will be found readable and interesting by students of physical science.

Deductive Physics. By FREDERICK J. ROGERS, M.S. Ithaca, New York, Andrews & Church. 8vo. 250 pp.

This book deserves consideration by all who are seeking a satisfactory college text-book of physics. It is in many respects different from any of the almost innumerable candidates for this distinction that have appeared during the past decade. Of these nearly every one has its merits and all have faults, but the variety is so great that the special necessities of almost every situation can be satisfied. There has been, however, a regrettable tendency in two directions. On the one hand, there have appeared several treatises very complete, very well prepared, but so large as to be really formidable and quite impossible of mastery in the time usually allotted to this subject in the college curriculum. The use of these compelled the adoption of the plan of omitting or 'skipping' many pages or even chapters, which is by no means to be commended under all circumstances. On the other hand, many college text-books are offered in which laboratory exercises are made so prominent as to seriously interfere with and often absolutely prevent a proper appreciation of the 'theory of physics.' Within a few years a few books have made their appearance in which both of these evils have been largely avoided and in which it has been attempted, as in the volume under consideration, 'to present, in compact though logically complete form, the principal facts, laws, definitions and formulas of the science of physics.' In the present instance the author has enjoyed a large measure of success. His definitions of fundamental terms and principles are, in the main, sound and discriminating. Although the discussions are generally concise, they are generally satisfactory, and no important phase of the subject has been entirely omitted. The illustrations are diagrammatic and clear and the leading propositions are illustrated and enforced by well-selected problems. No attention is given to experimental or laboratory exercises, but it is assumed that these accompany the use of the book whenever possible. In the opinion of the writer the author has made a mistake, unfortunately not an extremely uncommon one, in introducing several unauthorized and not generally recognized names for derived units, such as *kin*, *gramkin*, *spoud*, etc. This tendency towards multiplication of unit names has little to commend it and there is serious objection to it. It was the unanimous decision of the Chamber of Delegates of the International Electric Congress of 1893 that in electricity and magnetism

it was unwise to increase unit names beyond the small number then well fixed in actual use. The subject has been much discussed and it is believed that the weight of authority is against it. The student of physics and mechanics often loses sight of the thing and its derivation when a distinctive name is given to it, and while it is extremely convenient to distinguish by names a few of the fundamental and most important units of measure the number should be kept at the lowest possible limit.

Problems in Elementary Physics. By E. Dana Pierce. New York, Henry Holt & Co. 12mo. 200 pp.

This book is intended for use in secondary schools along with some suitable text-book and with laboratory exercises. It contains a tolerably extensive series of problems illustrative of the quantitative character of the science and the exactness of its conclusions. They are, in the main, well selected and properly distributed. Occasional definitions, formulæ or brief explanations are inserted, intended to be suggestive of the principles involved in the solution of the problems. Some of the problems and statements are open to a criticism applicable to nearly all text-books of this class. They are mostly written by teachers in preparatory schools who have never themselves (it must be inferred) enjoyed a very thorough training in physics. This is shown in the common failure to recognize the *limitations* to which almost all laws are necessarily subject, or the restrictions which must guard their enunciation. It is impossible, of course, to assume that the teacher of elementary physics should know all of these, as it is impossible for the college professor, who is a specialist in the subject, to know them, but it is not impossible to avoid some of the more common errors of statement, and it would be of enormous value if both teacher and pupil could know and never forget that most of the simple statements of physical laws, either by word or by formula, imply a simplicity of condition which never actually exists in nature. It requires some knowledge, but not much extra time and trouble to guard instruction in this line and the result is worth many times the cost. The lack of this is shown in a certain 'cocksureness' in elementary text-books and laboratory guides, as to what will or will not happen if you do so and so, and because the thoughtful and careful student is very likely to find that if things do *not* happen as described he is in danger of losing both confidence and interest. Nearly all books of the class under consideration abound in examples of this sort of thing. Instruction in physics in the secondary schools under the newer or laboratory methods is by no means the success that it is represented as being by those who have been its most active propagandists and the difficulty is not so much that lack of accurate scholarship has made a rigorous presentation of principles impossible, but rather that the great underlying philosophy of inductive science has continued unknown to both teacher and pupil.

M.

Insect Life. An introduction to nature-study and a guide for teachers, students and others interested in out-of-door life. By John Henry Comstock, Professor of Entomology in Cornell University and Leland Stanford Junior University. With many original illustrations, engraved by Anna Botsford Comstock, member of the Society of American Wood Engravers. New York, D. Appleton & Co. 1897.

In the college education of the present time nearly all science teachers are agreed that the introduction to natural history studies should begin in the lower schools, that instruction in biology should be as much a matter of requirement in the preparation for college as the study of foreign language. Many instructors of science in the colleges, while thoroughly believing that the principle is an excellent one, are not at all enthusiastic in the enforcement of such requirements, since natural history instruction in the preparatory schools is, as a rule, lamentably bad. A few perfunctory lessons in plant analysis, with neither enthusiasm nor knowledge on the part of the teacher, and much book work by rote is the rule rather than the exception, at least in the Western schools. It hardly matters what the boy or girl studies, so long as it is living organisms, if studied in the right way, and the right way is nature

itself. The training of the observational faculties is what the college instructor in natural history more especially desires in the preparation for higher work, and it matters little whether that training has been obtained in the study of botany, zoology, physiology or geology.

In the little work that has recently been published by Professor and Mrs. Comstock another step in the right direction has been made. The material for instruction in entomology is everywhere at hand, summer and winter, and for its abundance, diversity and instructiveness is unexcelled in any department of elementary biology; and 'Insect Life' has made the way plain for this elementary instruction in high schools and the higher grades of the grammar school under intelligent teachers. The work is an introduction to the study of animal life, calling for direct observation on the part of both teacher and pupil, and it is a better text-book for elementary instruction than any general work on botany or zoology can be, for classification is only an incidental part of the book. Excepting a few elementary chapters on the anatomy, metamorphoses and classification of insects, nearly the whole book is devoted to nature-study of the more familiar insects in their own haunts and in the laboratory. The concluding chapters tell in simple language how to prepare and preserve specimens for the cabinet. The pupil is encouraged to make a special study of some branch, and there can be no question but that such special study will do more to quicken his powers of observation and his enthusiasm than any amount of generalizations. The book fills a unique place in entomological literature and is to be highly commended. It is written simply and is fully and admirably illustrated by Mrs. Comstock.

S. W. W.

SOCIETIES AND ACADEMIES.

BIOLOGICAL SOCIETY OF WASHINGTON. 279TH MEETING, SATURDAY, OCTOBER 9TH.

MR. L. O. HOWARD exhibited a specimen of the Giant Water Beetle of Cuba.

Mr. R. T. Hill, under the title 'Notes on Antillean Faunas, Past and Present,' gave a resumé of his studies on the geology of the region, describing the various upheavals and subsidences that had taken place and their effects on the fauna of the West Indies and particularly of Jamaica. He stated that communication between the Pacific and the Gulf of Mexico was cut off much earlier than had been generally supposed.

Professor Barton W. Evermann spoke of 'The Catfish of Louisiana,' stating that few were aware of the extent of the fishery, 2,000,000 pounds being shipped annually. Two species were taken, *Ictalurus furcatus* and *I. nigricans*, the latter species having for some time been regarded as belonging to the genus *Amiurus*. During low water the fishes were taken in the bayous by means of extremely long trout lines, but during high water they were taken in the flooded woods, mostly on single lines.

Dr. Theo. Gill discussed 'The Inadequacy of the Order Bunotheria,' stating that the group was not a natural one.

F. A. LUCAS,
Secretary.

NEW YORK ACADEMY OF SCIENCES, SECTION OF GEOLOGY, OCTOBER 18, 1897.

THE first meeting of the Section for the autumn was largely devoted to accounts by various members of the scientific meetings of interest held during the summer. President Stevenson spoke briefly of the work of the International Congress of Geologists at St. Petersburg. The Secretary spoke of the work of the Geographical Section of the British Association for the Advancement of Science, at Toronto, and Professor Martin gave a similar account of the work of the Geological Section at the same meeting. The principal paper of the evening, apart from these descriptions, was by Mr. Charles Bullman, who gave a descriptive account of the location and character of the auriferous gravels of the State of Colombia, illustrated by many specimens. In the opinion of the speaker, the auriferous gravels are of wide distribution and thickness, and of exceeding value, and much more extensively distributed than stated by Mr. F. C. Nicholas, who gave a paper before the Academy on the same topic at one of the spring meetings. The speaker believes that the gold deposits are still being laid down with consider-

able richness and that the whole area around the San Juan river is extremely rich in auriferous deposits. The paper was discussed by Mr. Nicholas, who reiterated his statements that the gold-bearing clay deposits are not as extensive as they at first may seem to be, and that they are isolated to a few small localities now being dissected and drained by small streams.

RICHARD E. DODGE,
Secretary.

ANNUAL MEETING OF THE NEW YORK SECTION OF THE AMERICAN CHEMICAL SOCIETY.

THE annual meeting of the New York Section of the American Chemical Society was held at the College of the City of New York on Friday evening, October 15th, Dr. William McMurtrie presiding and fifty-two members present. The result of the election of officers for the ensuing year was as follows: Dr. William McMurtrie, Chairman; Dr. Durand Woodman, Secretary and Treasurer; Drs. C. A. Doremus, A. C. Hale and A. A. Breneman, Executive Committee; Dr. McMurtrie, C. F. McKenna and Marston T. Bogert, Delegates to the Scientific Alliance of New York.

Brief remarks were made by the Chairman on the death of Dr. M. Alsberg, one of the eight original founders of the Society, and an obituary notice by Dr. H. Endemann was read by the Secretary.

A paper was read by Professor P. C. McIlhiney on 'Some Experiments on Thermo-electric Pyrometry,' in which a very expensive form of electric pyrometer was described and directions given for its arrangement. Dr. McMurtrie made an address on 'Recent Progress in Industrial Chemistry,' after which a vote of thanks was unanimously passed to the Chairman for his faithful and energetic efforts during the year to make the meetings interesting and successful.

DURAND WOODMAN,
Secretary.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of Science of St. Louis, held on the evening of October 18, 1897, the Secretary presented in abstract a paper by Frank Collins Baker, entitled 'The Molluscan Fauna of Western New York,' dealing with specimens collected by the author between July 5 and July 29, 1897, and based on some 1,500 specimens, representing 75 species, and giving exact data concerning weather, temperature and altitude for each station in 19 different localities visited. The paper enumerates 146 species and 10 varieties, including those previously recorded for the section with which it deals. The lingual dentition of *Bythinia tentaculata* is described and figured, and several species have been subjected to critical review.

Professor H. A. Runicke made some informal remarks on recent progress in our knowledge of the constitution of steel, with reference both to its microscopy and chemistry.

WILLIAM TRELEASE,
Recording Secretary.

THE GEOLOGICAL CONGRESS AT ST. PETERSBURG.

THE Seventh International Geological Congress convened at St. Petersburg, Russia, on August 29, 1897, in accordance with the Czar's invitation, presented at the Fifth Congress in 1891.

The enrollment far exceeded that of any previous Congress, the preliminary list showing 966 names, of which only 270 were of Russians. The final list has about 1,100, about 120 of them being American.

The arrangements were upon an imperial scale. Free transportation on all Russian railroads was provided not merely for the members, but also for their families. Excursions were given such as no other Congress can expect, unless, indeed, another meeting be held in Russia. A guide book of 660 pages, with many maps, plates and sections, was prepared, giving detailed information respecting the geology of regions to be visited, a most valuable contribution to geological literature, making accessible, to geologists all over the world, facts previously published for the most part only in proceedings of scientific societies and sealed up in the Russian language.

Three excursions preceded the Congress. That to the Ural Mountains, shared in by somewhat more than 200 members, was in charge of Dr. Tschernychew and lasted for four weeks. This, extending beyond railroad and all other ordinary means of trans-

portation, afforded opportunity for the study of localities almost inaccessible to travellers. That the journey was completed with so little discomfort and with so great advantage to those taking it reflects great credit upon Dr. Tschernychew's management. The excursion to Finland, in charge of Dr. Sederholm, was taken by somewhat more than 100. That region is not so far in miles from civilization as is that of the Urals, but the perplexities of one in charge of a large party are hardly less. The success of this excursion was complete, and Dr. Sederholm earned the gratitude of those who accompanied him. The Esthonia excursion, under Dr. F. Schmidt, had only twenty-five members, but, according to the testimony of them all, the two weeks were spent pleasantly and with great profit.

A fourth excursion began on September 5th, at the close of the Congress. This was to a more distant part of the empire, extending to the Caucasus and in one division to Mt. Ararat.

During the week allotted to meetings of the Congress, two days were given to excursions. One to Peterhof, the summer palace of the Czar, was for pleasure only; the other, combining pleasure and instruction, was to the Falls of Imatra—a long excursion in short time. The excursionists left St. Petersburg at 6:30 a.m. and reached the Falls at 1 p.m. They remained there until 7 p.m. and then returned, reached St. Petersburg at 1 a.m., thoroughly fatigued for the most part, but well repaid. The hospitality in the city began to manifest itself on the evening prior to the assembling of the Congress, when the Committee of Organization gave a reception to the members at the Germania club. On August 30th the Grand Duke Constantine gave a reception at his palace to about 200 delegates and the Mayor of the city held a grand function at the Hotel du Ville on September 2d.

The Congress was opened at noon on August 29, 1897, in the large hall of the Zoological Museum of the Academy of Science. Addresses of welcome were delivered by the Grand Duke Constantine, the Princess of Oldenburg and the Minister of Agriculture, to which Professor Capellini replied on behalf of the Congress. The list of officers prepared by the Bureau was read by Professor Renevier and chosen by the Congress, after which an address was made by Professor Karpinsky, the President, who was followed by Dr. Tschernychew, the Secretary-General, who outlined the business which would be presented by the Council. A brief address by the President of the Geographical Society closed the exercises and the Congress adjourned for the day.

The Congress sat twice each day on Monday, Wednesday, Friday and Saturday. The morning sessions were devoted to discussion of principles of nomenclature and to transaction of such matters as were presented by the Council, while those of the afternoon were taken up in the reading of memoirs.

The morning discussions were simplified greatly by the memoirs of Bittner, Loewenson-Lessing and others prepared at request of the committee and printed prior to the Congress. It must be conceded that the results of these discussions do not appear at first glance to be of very great importance; the points agreed upon were such as impose no burdens and they were adopted unanimously. But where the question proved to be serious and material differences of opinion seemed likely to develop, the matter was referred to a committee for consideration and for report to the next Congress. This, however, was the wisest mode of procedure. The Congress has no power to bind its members except in so far as they consent, so that it is not the place in which to thrust one's conceptions too

strongly. Any matter which does not commend itself readily at the first presentation should be laid aside promptly, that no member be allowed to express himself in such manner that his *amour propre* would be wounded in case the vote should go against him. All of the matters referred will be considered carefully by the committee as well as by a great part of the membership during the next three years, and there will be little difference of opinion respecting important matters at the Congress of 1900.

The reading of memoirs was somewhat perfunctory, or rather the listening was so. The feeling seemed to be that these would be printed and that members would have opportunity to digest them at leisure. Several reports were presented by committees, and they will be published in the volume of proceedings. A committee was appointed to consider the principles of chronological classification of sediments and another to consider the propriety of establishing an international journal of petrography. The Congress expressed itself as earnestly favoring the establishment of a permanent floating institute to carry on work such as that of the Challenger expedition, and also as favoring the developing of geological courses for higher classes in lycees and gymnasia. The members were called upon to urge these matters upon their governments.

The Congress adjourned on September 5th, to meet in Paris in 1900.

The real value of this as of previous Congresses is not to be measured by the list of memoirs or by the records of discussions. Important as those may be, they are of vastly less importance than the actual contact of men coming from all parts of the world. Geologists from Asia, the Pacific islands, the Americas and almost all nations of Europe met together; too often known to each other previously only as streaks of printers' ink, they became actual entities; those devoted to similar studies found opportunity to compare observations; many, whose conceptions of phenomena were limited by the little area of their country, have gone home with a broader knowledge; and a long step has been taken toward binding together our men of geology. The true work of the Congress was done not so much in the sessions as in the huge lobby, wisely provided, where those of like minds were gathered in little clusters making liberal dividends of knowledge. This feature was recognized as all important by the Committee of Organization, which, with this in view, planned the excursions on which so much of the real work was done.

To speak of individual members of the Committee of Organization as especially worthy of remembrance may seem ungracious when all were so untiring, but one cannot refrain from acknowledging the indebtedness which all must feel to Karpinsky, Tschernychew, Nikitin, Chrustchoff and Michalski, while the Americans will remember pleasantly the courtesies rendered by Mr. Gardiner, the only American student in the University of St. Petersburg.

JOHN J. STEVENSON.

NEW YORK UNIVERSITY.

A NEW INVESTIGATION OF MAN'S ANTIQUITY AT TRENTON.

I.

A RENEWED search for evidence of glacial man at Trenton induced Professors G. F. Wright and Arthur Hollick, Messrs. H. B Kümmel and G. N. Knapp, of the New Jersey Geological Survey, and myself, on June 25, 26, 27 and 28, 1897, to explore a site on the summit of the glacial gravel terrace at Trenton, where Mr. Ernest Volk*

* Working under the direction of Professor F. W. Putnam for the New York Museum of Natural History, Mr. Ernest Volk was generally present at the

has alleged the discovery of artificial argillite flakes, and other relics of human handiwork, in a yellow sand of supposed glacial age under a surface loam stratum indicating Indian occupancy.

Five trenches (Trench A, $21\frac{1}{2}$ ft. by $3\frac{3}{4}$ ft. by 3 ft. 3 in. deep; B, $7\frac{3}{4}$ ft. by $4\frac{1}{2}$ ft. by 3 ft. 3 in. deep; C, 6 ft. by 6 ft. by 2 ft. 8 in. deep; D, $4\frac{1}{2}$ ft. by $4\frac{1}{2}$ ft. by 3 ft. 3 in. deep), sunk over an area 90 ft. long by 33 ft. broad,* well upon the flat summit of the terrace, with Trench D, about 80 ft. from the outer brink, revealed clearly:

Layer 1.

(10 inches to one foot).

A discolored surface loam, disturbed by recent cultivation, mixed with the remains of the Indian and white man. It contained:

	Specimens.
Blocked-out blades, Argillite	3
Blocked-out blades, Chert	2
Argillite blade, long, narrow (spear form)	1
Arrow-head, broken, Jasper	2
Arrow-head, broken, Chert	1
Hammer stone, pebble, fragment	1
Animal bones, with large scapula, probably Elk splintered limb bones and limb bone of a bird	22
Mussel shell (Unio) fragments	6
Pebbles, probably fire-cracked	131
Teshoa or pebble flake, scraper?	1
Argillite flakes, probably artificial, generally with green patina	19
Chert flakes, probably artificial	11
Jasper flakes, probably artificial	5
Stone (unidentified) flakes, probably artificial	6
Quartz and Quartzite fragments	5
Potsherds, Indian (8 found together)	9
Pebbles unworked; size, from that of robin's egg to goose egg; largest 4 in. in diameter	55
Miscellaneous stones, mostly pebble fragments	103
Oyster shell	1
Cinder fragment	1
Anthracite coal fragments	2
Glazed potsherds	2
Brick fragment	1

Below layer 1, and as the chief center of observation and interest, rested

Layer 2.

(18 inches to 2 feet).

Composed of a fine yellow sand, streaked towards its lower portion with fine irregular films of reddish sandy clay which thickened and coalesced at the bottom into a distinct harder red band.

Advancing slowly into layer 2 with trowels against the sides of the trenches where the stratification had been exposed in vertical section, we pulled out one by one the pebbles, broken stones and artificial chips, etc., described below, giving special attention to the large pebbles and the chips most artificial in appearance, calling the attention of all our colleagues to each large object, when it first clinked against the trowel's edge so that its depth could be measured and its position with reference to the clay films, observed by us all before its removal.

The objects thus found (after discarding those resting in the upper part of the layer for about four inches below the bottom of layer 1 as pertaining to what we called the zone of doubt) were as follows:

ARTIFICIAL FLAKES.

NOTE.—The numbers in inches after the specimens indicate the depth in Layer 2 below the zone of doubt, the letters the trench referred to.

	Number of Specimens.
Jasper, 10 in.	1
Jasper, 12 in.	1
Quartz, 4 in	1
Argillite green patina, $6\frac{1}{2}$ in	1
Sandstone or Argillite, $2\frac{1}{2}$ in	1
Argillite lying flat, $3\frac{3}{4}$ in	1

digging and hospitably offered us every assistance, being seconded by the kindness of the owners of the property, the Misses Lalor, who generously placed their land at our disposal. Dr. Charles C. Abbott was continually present, and Dr. Harrison Allen, of the Academy of Natural Sciences, of Philadelphia, visited the Trenches on Sunday, June 27th.

* Kindly reserved for our use by the Misses Lalor, owners of the property, for whose generous hospitality we herewith return our thanks.

Argillite, 7 in 1
Jasper, 12 in 1
$1\frac{3}{8}$ *in. wide,* $\frac{1}{8}$ *in. thick, Trench A 2 in. resting on its side below a thin film of reddish clay. The film waved from one side of the trench to the other over the specimen, becoming slightly thinner and fainter directly above it, though without showing signs of break. Photographed in place, 20 in.* See Figs. 1 and 3 1
Argillite green patina, about 1 in. in diameter, possibly artificial, resting exactly in line of clay film, 12 in 1
Quartzite, possibly artificial, 8 in . . . 2
Chert (resting indubitably in films of sandy clay. Trench B. Photographed in place,

FIG. 1.—View of face of Trench A, showing Argillite specimen (see middle right-hand specimen in Fig. 3, Professor Hollick's paper) resting in place, 20 inches down, in the yellow sand at base of the rule. The trowel scratch marks the position of the film of stratification just above the specimen. The lower scratches mark the thickening of these films at the base of the yellow sand. From surface to trowel, Layer 1 (Indian), ten inches to one foot. From trowel to series of scratches, Layer 2, yellow sand, relic bearing, eighteen inches to two feet. Below scratches coarse sand and gravel, non-relic bearing. Specimen photographed in place June 26, 1897, by Ernest Volk, in presence of G. F. Wright, H. B. Kümmel, C. C. Abbott and H. C. Mercer.

signed G. F. Wright, Arthur Hollick, H. C. Mercer). See Figs. 2 and 3 (in Dr. Hollick's paper), 12 in. 1
Flakes Argillite, small below clay film, Trench B., 14 in 1
Quartz, Trench B., 8 in 2
Quartzite pebble, 10 in 1
Argillite, possibly artificial C., 12 in . . 1
Quartzite, possibly artificial C., 10 in . . 1
Jasper, possibly artificial C., 6 in . . . 1
Argillite, possibly artificial C., very small piece, $2\frac{1}{2}$ in 1
Chert from pebble, 6 in 1
Argillite, possibly artificial, 3 in. long by $1\frac{3}{4}$ wide, green patina under a very distinct film of reddish sandy clay, Trench C., 19 in 1
Argillite, possibly artificial, exactly in line of heavy red film and 6 in. below fainter film C., 16 in 1
Quartz, possibly D., 6 in 1
Chert from pebble, 6 in 1
Argillite, probably artificial, bedded in filmings of reddish sandy clay not immediately overlaid by a continuous film, but rather by faint reddish broken streaks D, 15 in 1
Argillite patinated, $2\frac{3}{4}$ in. long, $1\frac{1}{2}$ in. wide, $1\frac{1}{8}$ in. thick, probably artificial, resting in series of clay films less clearly marked than in the other trenches, but nevertheless extending over the specimen in a series of blotches, D, 16 in . 1
Argillite piece, possibly artificial, on film, 15 in 1
Argillite piece, possibly artificial, on C, 12 in 1

CONCLUSION.

Fifty stone flakes mostly man-made, not of argillite alone, as we had been led to expect, but of argillite, chert, jasper and quartz, one battered pebble and two fragments of anthracite coal, thus positively

found in the much discussed stratum of yellow sand which we have called Layer 2, present us with interesting evidence as to the relation of the sand stratum to man; while in the further presence of twenty-three miscellaneous stones, and two hundred and fifty-four water rolled pebbles, ranging in magnitude from the size of a chestnut to that of an ostrich egg, we are confronted with interesting considerations as to the deposition of the sand, whether by wind or water.

The antiquity of man, at the site, judged by these observations, depends on three questions:

1. *Are the significant chips in the yellow sand artificial?* To which my experience answers yes.

2. *Are they in situ in the yellow sand?* To this I would say that the notion of the intrusion of objects from the Indian surface layer above (Layer 1), down and into the sand below (Layer 2), is suggested to me for the following reasons: Because the deepest artificial specimen in the yellow sand (Layer 2), rested not over three feet below the surface; because the range of stone chips (argillite, jasper and quartz) and fractured pebbles was identical in the yellow sand (Layer 2), and the Indian Layer (Layer 1), and showed thickest under the latter, growing thinner downward; because argillite chips identical in character and equally decomposed and patenated occurred in both layers; because two pieces of anthracite coal were found in the upper part of the sand (Layer 2), and, lastly, because the artefacts were scattered at irregular depths in the sand (Layer 2), nowhere suggesting by their collocation a floor of occupancy or workshop abandoned by primitive man.

On the other hand, neither the shallow depths of the objects nor the closeness of the layers exceeded conditions known to archæology where divergent culture epochs had been found to rest closely one upon another. And while no potsherd or bone was found below (in Layer 2), the similarity of the stones used where the blade material (ingredient to glacial gravel) had continually remained the same failed to overweigh the probability of antiquity as to the specimens from the lower layer. Coal fragments not uncommon in the alluvium of the Delaware, whose trough traverses coal beds near Mauch Chunk, had been found by me in an underplaced Indian village layer, probably pre-Columbian, at Upper Black's Eddy,* while the observed position of roots and the study of small ant galleries failed reasonably to account for the site of the chips in Layer 2, whose position in several cases beneath well observed and unbroken films of stratification remained the most important fact in the evidence.

When all was considered I was forced to conclude that a significant number of artificial chips rested in situ in the sand, and hence were of an age antedating its deposition.

Here again, as at the underplaced layer at Lower Black's Eddy, we were confronted by two thin strata of human occupancy, resting one upon the other, but separated from each other by an interval of time as yet unmeasured.

Antedating the familiar Indian, preceding the birth of the known riparian forest as indicated by the superficial blackness of its plant-stained loam, the immediately underplaced yellow sand Layer 2, close beneath the surface as it lay, testified to the previous presence of a chipper of argillite, jasper and chert, and a bruiser of pebbles, upon the surface of the bluff. As before remarked, the bones of animals and pottery, characteristic of the upper layer, were ab-

* See researches upon the antiquity of man in the Delaware Valley and the eastern United States. Publication of the University of Pennsylvania, Vol. VI., p. 78. Ginn & Co., Boston. 1897.

sent in the lower; otherwise, no marked difference appeared in the kind of stones used, their patina, or mode of fracture.

From the evidence previously produced by the more notable explorations of the Trenton site, the present testimony differs in several particulars. The shallow zone of discovery, ceasing at about three feet below the surface, failed to encroach upon the region (10, 20 and 30 feet deep in the immediately underplaced gravel) alleged as the horizon of previously excavated human relics. No series of ovate blades resembling the drift specimens of France and England appeared as in previous years, to out-classify all other objects; while the contention (unreasonably over-valued in our opinion) in favor of the absence of jasper in earlier human horizons was not sustained by our discoveries. Nevertheless the existence of man upon the bluff top under topographical conditions differing from those of the present had to to be admitted.

This granted, however, the question of human antiquity at the site depended not so much upon the evident priority of the sand relics to the Indian remains of the surface loam as upon the length of time of such priority—namely, upon the final space question:

3. *What was the age of the sand?* Extending outside the province of my qualification, this question remained to be settled by my colleagues. Let their special experience decide whether this yellow layer resting exactly upon the Trenton gravels is a true part of their composition. Was this overlying sand the work of the river swollen to excessive volume by the melting of the great glacier? Had modern rivulets, since drained away, spread it upon the terrace top? Or, during the time before trees grew and loam formed, had wind whirled it, pebbles, clay films and all, upon the even table of the bluff?

Henry C. Mercer.

II

On June 25th, by invitation of Professor G. Frederick Wright, the following party met at Trenton, N. J., to make excavations in the Trenton gravel terrace, and to examine any archæological material which might be brought to light: G. Frederick Wright, Oberlin, Ohio; H. C. Mercer, Doylestown, Pa.; C. C. Abbot, Trenton, N. J.; Ernest Volk, Trenton, N. J.; Arthur Hollick, Staten Island, N. Y., and a workman to perform the rough digging.

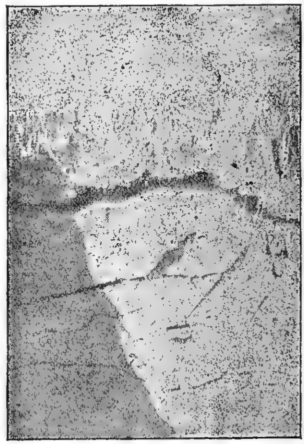

Fig. 2. Artificial chert specimen (see also upper right-hand specimen, Fig. 3, on next page) photographed as found in place in the yellow sand. The trowel scratches show the line of films of stratification above and below the object. The dark, deep scratch marks bottom of Layer 1 (Indian), 10 inches to 1 foot. Yellow sand, Layer 2, extends downward from heavy trowel streaks. Photographed by Mr. Volk in the presence of Professor Wright, Dr. Hollick and Mr. Mercer.

Through the kindness of the Misses Lalor, a part of their farm, favorably located on the edge of the terrace, had been reserved for investigation. Upon the surface of this part an area about forty feet long in a north

and south direction, by about four feet wide, was selected by our party for excavation. Our workman first removed the surface soil by spading and shoveling, to a depth of about six inches, and threw it to one side. This soil was found to consist of a fine yellow-brown sand, mixed with humus and other carbonaceous matter, which gave it a prevailingly dark color. All objects thrown out with this soil were collected and listed tery; unclassified stones, mostly broken or chipped. The entire collection apparently represented the ordinary refuse of an Indian camping ground, with a few indications of modern civilization.

At the southern end of the area from which the surface soil had been removed, a pit was excavated 4 ft. by 4 ft. by $3\frac{1}{2}$ feet deep. The sides of this pit were carefully squared and showed the following section:

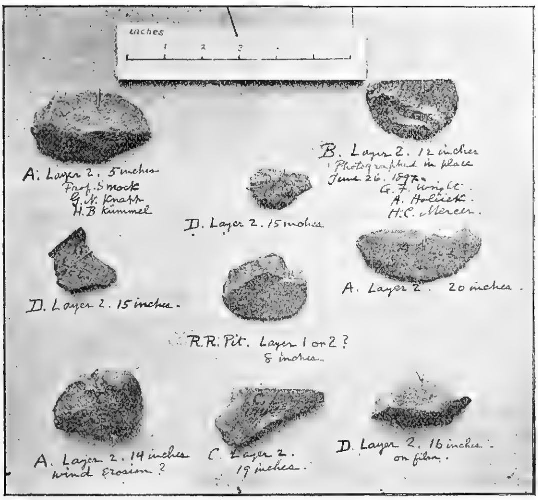

FIG. 3.—Weathered pebble, artificial flake of chert and flakes of argillite, described in the text, except one on the upper left-hand corner, found at significant depths in the yellow sand, sometimes upon or under filmings of stratification, by Professor Wright and Dr. Hollick, Professor Smock, Messrs. H. B. Kummel, G. N. Knapp and H. C. Mercer.

under 'A' and 'B;' the first representing the preliminary spading, the second the shoveling.

The objects consisted of fire-cracked stones; unworked pebbles, from size of a cobble to that of a robin's egg; chips and flakes, mostly of chert, but a few of argillite; rejects; imperfect implements; a fragment of anthracite coal; a cinder; a piece of oyster (?) shell; a piece of modern pot-

1. Disturbed surface soil, consisting of fine yellowish-brown sand and black carbonaceous matter, giving it a prevailingly dark color, 8–12 in.

2. Undisturbed fine yellowish sand, irregularly stratified, with streaks of red sandy clay carrying small pebbles, 2 ft. 6 in.

3. Floor of red sandy clay at bottom.

The line of demarkation between the disturbed surface soil and the undisturbed

sand could not be sharply drawn. Streaks and small pockets of black soil often extended down irregularly into what was apparently undisturbed sand. A zone was therefore recognized, below the disturbed surface soil, which we agreed to call the 'zone of doubt.' All implements or objects found in this zone were listed under 'C.' The bottom of the 'zone of doubt' was about 18 in. below the surface of the ground.

Below the bottom of the 'zone of doubt' we agreed that the sand was undisturbed by human agency and that any objects found there must be regarded as having been deposited at the same time with the sand, or possibly intruded from above, in which case some evidence or indication of such intrusion should be apparent.

The following method of investigation was then pursued:

One person entered the pit and gradually cut away the face with a trowel. As soon as any object was struck the rest of the party were notified and the sand around it was carefully removed. The distance from the bottom of the 'zone of doubt' to the object was measured and the object was then removed and examined. Each such object was immediately wrapped in a separate piece of paper, together with a memorandum of the facts in connection with it.

NOTES.

As far down as we dug we found roots of living trees, larva of June bugs (?), ants, and occasional disconnected spots or streaks of dark matter, which I took to be the remains of old decayed roots.

The undisturbed sand was found to be distinctly stratified and evidently a water deposit. Pebbles and gravel grains were not uncommon, especially in connection with the clay seams, and nearly all the chips and implements found were lying flat, although a few were more or less on edge.

Nothing but rough chipped implements (palæoliths?) and fragments were found below the 'zone of doubt' up to the time when I left (4 p. m., Saturday, June 26th), when about one-half of the main excavation had been made.

Supplementary pits were also started close to the main excavation in order that others of the party might be occupied in digging at the same time. The methods employed were identical in each case.

We failed to verify the contention that only argillite chips and implements are to be found in the undisturbed sand. Some jasper, chert and quartz flakes were also found, but argillite was the most abundant material represented.

One fine chert implement was photographed in place. The details in regard to this and other objects found in the undisturbed sand are described by other members of the party.

CONCLUSIONS.

The writer accepts the conclusions of competent authorities that the so-called palæoliths are of human manufacture and that the sand in which they occur is of glacial age.

After a careful examination there seems to be no doubt that this sand is a water deposit and that it had not been disturbed by human agency prior to the time when it was excavated by our party.

The only controversy which seems possible is over the question of intrusion from above and, in view of the facts now adduced, the burden of proof should in fairness rest with those who hold this view.

ARTHUR HOLLICK.

---

*DIVERSITY OF LANGUAGES.**

THAT type of civilization cannot be regarded as ideal or forethoughtful which

*Concluding section of the address on 'Improvident Civilization' by the Vice-President of Section I., Social and Economic Science, American Association for the Advancement of Science, Detroit, 1897.

tolerates a wide diversity of tongue in which to conduct its business or store up its ideas and valuable records. As already stated, difference of speech and writing tends to keep nations and races estranged, and so makes for war rather than peace. The only progress toward a uniformity of mother tongues now visible is by the slow and fitful process of political absorption by conquest or by trade. Singularly enough the acknowledged languages of learning, the Latin and Greek, seem to be losing rather than gaining their hold upon the best literature. This is not altogether a misfortune; for languages grow and expand to conform to the ideas of those who use them; and the original connotations of words are lost in their adaptations to new conceptions. In spite of the attempt to uphold the Roman tongue by the medical and priestly professions, it is no longer that spoken by Cicero. The English of to-day differs widely from that of Chaucer. But few famous treatises in science, philosophy, history or even theology are now written in Latin; other tongues command more readers, and it no longer so well serves as a vehicle for modern ideas. No language can escape this fate. The English, which is conceded by competent observers to be as rich, as flexible and precise as any of the great European tongues—though not as simple and symmetrical as some others—has embalmed in it quite as many of the indispensable works of the world, and has besides the suffrages of a hundred and twenty millions of people to whom it is vernacular, is nevertheless susceptible of great rectification, especially in the matter of pronunciation, spelling, and in the irregularity of the verbs. The testimony of Professor Merz, in writing of 'Scientific Thought in the 19th Century,' although strangely oblivious of American contributions, as such, uses the following language, after referring to the decaying use of the classics:

"The largest number of (Scientific) works perfect in form and substance, classical for all time, belongs probably to France; the greatest bulk of scientific work probably to Germany, but of the new ideas which during the century have fructified science the larger share belongs probably to England. Such seems to be the impartial verdict of history. During the second half of the century a process of equalization has gone on which has taken away something of the characteristic peculiarities of earlier time. The great problems of science and life are now everywhere attacked by similar methods. Scientific teaching proceeds on similar line, and ideas and discoveries are cosmopolitan property. So much more interesting must it be for those who have been born members of this international republic of learning to trace the way in which this confederation has grown up, what have been the different national contributions to its formation, and how the spirit of exact science, once domiciled only in Paris, has gradually spread into all countries and leavened the thought and literature of the world."

Nevertheless the hope of establishing either Latin or Greek as alternative world-languages, of learning, has not been abandoned among the classically educated; but all expectation of seeing the former generally adopted, at least as a spoken tongue, must have passed. If the great start of the Roman Empire, and the subsequent extension of its speech over a larger empire by the Church, did not suffice to give it precedence the chances are much against it now. Like the Roman jurisprudence it lives chiefly in its offspring. It has been more or less engrafted on the native tongues; itself is practically a dead language. The Greek survives among living tongues, but has only a limited field as such. In scientific and classical education, and notably in nomenclature, it has a future of utility as an enricher. Some of the international medical conferences are, I believe, ready to adopt it as an alternative language for their limited uses.

Meantime the business of the world becomes more and more international and interlingual. The spread of telegraphs by land and under seas, the extension of steam-

ships and steam railways across frontiers, sometimes across several of them, not only crowd the nations together, but some common code of communication between them is a desideratum—the world of commerce no less than that of letters and research waits for it. Regulation for navigation on the high seas have been contrived by the maritime nations and adapted to all; we have likewise a growing communication and conformity in astronomical, chemical and electrical literature; uniformity of standards of weight and measurement, mechanical devices and the like. In a small way, too, we have a universal language in musical notation; in the telegraphic alphabet, in the deaf-mute and in algebraic signs. How much longer will the international requirements of the whole world have to wait before a real world-language is hit upon? Must we wait until the struggle for political boundaries of the dozen or twenty several nations of Europe has concentrated the smaller ones into one dominant prodigy? If not, when and how shall the movement be begun and carried out, and by whom? The time seems to be ripe for a practical consideration of these questions, and it concerns some association of learning to do so; and for several reasons the initiative would seem to be left with the Department of Social and Economic Science.

I need not enlarge upon the magnitude of the continuing loss from the present diversity of tongues, not only in the time and effort spent in acquiring several languages, when one beside the vulgar tongue might answer all purposes of education, if that other alternate tongue were common to the great civilized nations. The waste is still greater from the publication of researches, laws, treaties and records in several dresses, all of which must be consulted by the student who would keep abreast of the advance of knowledge. The shelves of our libraries are being piled high with books of all shades of usefulness and uselessness, and an extensive ransacking of bibliographies is required to master any given topic. The most of these have only ephemeral value, but this again adds to the burden. One good effect of an alternate language of learning would be the saving from this weary plowing of the sands; the truly classic works worth preserving would in a few generations be winnowed out and a lifetime would not be consumed in mastering the works of authors long superseded, but which, as they now stand mingled side by side, are indistinguishable. An *Index Expurgatorius*, by a scientific college *de propaganda fide*, is not in accord with modern notions, but it would be a great step in advance to have all science uttered in one language and reviewed in the same. When one thinks of the ten thousand volumes printed annually by the presses in English alone, one is tempted to sympathize with that Arabian Calif who ordered the great library of his time destroyed on the ground that it was either superfluous or heretical.

Observe, there is no suggestion to invent a new language such as Volapuk aspired to be. We all know languages grow by laws of their own, and are not run into a mold. They are, however, plastic and susceptible of enrichment and improvement by human contrivance. Instances are quite numerous where one tongue has supplanted another; and the example of two or more languages being taught and used concurrently is quite common. In fact, the task of imposing a second speech on a nation is much easier than that of imposing another religious cult, or a change of metallic money standards, either of which is still deemed to be feasible.

The growth of languages may be compared to the formation of common paths and roads through the primitive wilderness; at first following the trails of wild beasts; whenever a tree falls across the path it is deflected and so continues long after the

obstruction has crumbled away. The tendency to these deviations and doublings seems to be inherent. The French is about the only tongue which has an officially appointed guardian to keep it within orthodox lines; and it must be added that none needed it so much, or has so much to be done for it remaining. What is needed, and would seem to be practicable, is the application of modern methods equivalent to the work of the civil engineer among the time-worn paths—a leveling and alignment, the taking out of kinks and détours, and introducing great precision and definiteness. It is no greater task for our time than the change to the Julian calendar was for that, and is comparable with the proposition to divide the year into 13 months of days. I fear it is not the proper or congenial rôle for philologists and lexicographers whose task will come in at a later stage, in the perfecting and grafting upon the adopted alternate language. Thus far their special interest seems to lie in the diversity rather than the uniformity of tongues; and their very modest efforts to introduce a more regular spelling and pronunciation, though not entirely barren, are, by no fault of theirs, hopelessly slow of adoption. The chances of these reforms would be better if English could be adopted as a world-language; and if another were chosen they might be needless.

This Association is called upon from time to time to join in international conferences, to recommend or appoint delegates to such gatherings, and to pass upon their reports touching matters of nomenclature, classification and standards. The cause of learning has very much at stake in an extension of this same function to language. Other interests are also concerned, and whether these other interests—foreign commerce, diplomacy, telegraph or transportation—shall take the initiative, or leave it to others, there should be a joint action and representation. This subject is already attracting the attention of practical business men, who may be expected to move in the matter faster than the teachers and lexicographers. While writing, my attention has been called to an address by a business man to a Boston business club, advocating the use of English as a world language. A table quoted from Mulhall, showing the growth of the great European languages in the years 1801 to 1890, shows that the English has increased 217 per cent., while no other except the German has reached so much as 100. I have added to it a column of estimated numbers, using the same tongues at the present time, in which the lead seems to be with the English, though this is liable to be challenged by the partisans of Russia, as the official language, though not the native one, of a nearly equal number.*

Can we assume that this lead can be maintained for another century, when the Russian Empire shall touch the two oceans and the Mediterranean, or when the German Empire shall extend from the North Sea to the Bosphorus? If not, there is nothing to be lost, and much to be gained, for us, by an earlier rather than a later settlement of this queation.

There have also appeared in the daily press expressions from some learned society of Germany, which I am expecting to see authenticated any day, a willingness on

*INTERLINGUAL CONFERENCE.

Mulhall's Table of increase, 1801–1890. (% in 1801.)	(% in 1890.)	Millions spoken by in 1895. (Estimated.)	
12.7	27.7	English	120.
19.4	12.7	French	46.
18.7	18.7	German	37.
9.3	8.3	Italian	32.
16.2	10.7	Spanish	22.
4.7	3.2	Portuguese	15.
19.	18.7	Russian (?)	129.

		Scandinavian	9.
		Holland	5.

their part to adopt the English as an alternate world language, provided some necessary reforms were made in spelling and orally to make it more phonetic and conformed to the classic Latin and Greek. This is a very reasonable and fit concession to be imposed, and ought to be undertaken in our own behalf without regard to the propaganda. If, by some such concessions as these, the support of Germany, and perhaps also Holland, Scandinavia and Spain, can be won, the adoption of the English is assured; and we cannot too soon convene an international conference. The Germans are handicapped by a Gothic eye-destroying alphabet and an unmusical vocal speech, and are conscious of it. This is their opportunity and ours. The claim of the French as the established language of diplomacy is recognized in Europe, but, declining even there, would be outweighed even though supported by Russia. Opposition would be likely to come from that quarter, if from any; or from a possible coalition of all the rest against the leader. But fortunately this is a case in which there is no compulsion. No nation need be bound by any recommendation of the conference, if it thought it could do better to stand out. In brief it is the counterpart of the decimal metrical system; the advantages and drift of any action would be toward uniformity sooner or later. Professor Mahaffy is out in a very pronounced opinion as to the need of rectifying English; while Mr. Havelock Ellis, I perceive, is quoted as favoring French as a second choice.

My own idea about the manner of calling, and the composition of, such an interlingual conference is that, by virtue of her much greater foreign commerce, marine interests, including telegraph, postal, consular and diplomatic intercourse, the initiative would properly belong with the mother country. Any such call from her would be sure to suggest some antagonism, and, most likely, also she would be asked to content herself with one vote on behalf of Britain and all her colonies, and attempt might be made to link in the United States. I have no idea that representation according to aggregate population would be acceptable. The most feasible plan will be by nations, or groups of nations, the offshoots and colonies not being reckoned, except in the single case of the United States, which, if expedient, could speak for Canada, too. The position of North America is one of peculiar freedom from jealousies and entanglements, and if the mother country will for this occasion graciously let her full-grown settled daughter appear in the foreground there will be less friction to encounter, and the result will be the same in either case.

There is a certain fitness aside from its expediency. American lexicographers and philologists have done more for the improvement of English in a hundred years than the British. Besides, the number of universities and students and the literary output are now comparable in volume, if not in quality, with the older nation. The ultra-conservatism of British publishers is shown by an unwillingness to handle books by American authors using the abridged spelling of certain common words where the right of argument is on our side. Again, in Asia, especially in China and Japan, which are now open to Occidental literature, science and arts, we are side by side with the British and opposed by French and German influences. If I am rightly informed, Japan is most anxious for uniformity; in fact, would accept readily a common tongue, and prefer the English. The part to be played by these islanders of the far East in international affairs cannot yet be defined, but their alliance in these bonds of peace, civilization and learning is worth cultivating.

As a rough outline of the composition of

the first conference on an alternate common language for international trade intercourse, letters, science and arts, let us suppose that whenever a sufficient number of avowals of interest in the subject shall have been received from representative bodies an invitation shall be addressed by the Secretary of State of the United States, or by this Association, or some similar body, to like associations and guilds in the following countries to choose delegates to meet at some suitable time and place in central Europe:

1. Great Britain, including colonies and India.
2. United States of America and Canada.
3. Germany, not including Austria.
4. Austria and the Hungarian and adjacent Slav states.
5. France including her colonies and Belgium.
6. Spain and Portugal.
7. Italy.
8. Greece.
9. Holland.
10. Scandinavia (Denmark, Sweden and Norway).
11. Russia.
12. The Spanish and Portuguese republics of North and South America.
13. Japan (by courtesy, not voting).

Each of these units to be represented by, say, five delegates drawn respectively from the larger international interests:

A. Political—diplomatic and jurisprudence.
B. Scientific—mechanical and medical.
C. Foreign commerce and navigation.
D. Telegraphic, foreign exchange and postal.
E. Pedagogy, publishing and philology.

Here we may have a polyglot convention of say sixty-five persons, with sixty votes representing various pursuits. All that it need do is to pass resolutions, after preamble, recommending to their respective governments that it be made lawful on and after a certain date, say January 1, 1901, or as soon thereafter as may be, to use the language adopted, and that it shall be taught in all public schools as a second, or alternating, language; and further that all documents for interlingual use, such as passports, cable and telegraph blanks, navigation charts and astronomical codes, postage stamps, money orders, letters of credit, coins, tables of metric systems, shall be inscribed in both media. Similar action on the part of the guilds and institutions themselves would be sufficient to ensure the trial.

The work of simplifying the adopted tongue, so as to make it more acceptable and more easily acquired by the rest is quite another function, belonging to a different body, and can be reported on from year to year without limit of time. Our newest dictionaries contain already some thousands of minor and acceptable changes. It would greatly add to the regularity and euphony of the English (if it should be chosen) to incorporate and substitute freely from the Spanish as written (not, however, including the eccentricities of its pronunciation) in which case the Latin and Italian methods should be taken; in this way the good will of our neighbors on the American continent might be secured, with no detriment whatever to ourselves. Computations are sometimes made to show the enormous aggregate loss from the use of redundant or silent letters in writing and typesetting. This economy is easily embraced within the larger reform outlined above.

If it is the pleasure of the Section, during this meeting, to take any action on this subject, it will give us pleasure to urge it before the Council.

RICHARD T. COLBURN.
ELIZABETH, NEW JERSEY, U. S. A.

APPENDIX.

The following resolution was subsequently adopted by the Council, and copies ordered printed for corresponding societies, universities, etc.:

WHEREAS this Association is from time to time called upon to recommend or choose delegates to international conferences seeking to promote uniformity in scientific classification nomenclature, metrology, publications, and is likewise interested in uniformity of navigation and postal regulations, and researches

at present recorded in several differing European languages; and

WHEREAS the diversity of tongues is a continuing hindrance to interchange of knowledge and literatures, seriously enhancing the cost and labor of studious pursuits, which might in large measure be avoided by the adoption by the civilized nations of an Alternate Language of Learning, Law and Commerce, and as such required to be taught in higher schools (in combination with the mother tongue) and used in interlingual correspondence and printed records; and

WHEREAS it is believed this need is felt and acknowledged by societies and corporations of several nations and awaits the initiative of some one of them to propose concerted action thereon; now, therefore, be it

Resolved, That whenever the President or Permanent Secretary of the Association shall have received from similar bodies, or from universities of Europe, expressions sufficient in number to represent a majority of the maritime peoples, signifying a desire to cooperate in an International Conference of Languages, it shall be his duty to lay the same before the Council at the next regular, or, if neeed be, at a specially-called, meeting, with the view to the appointment of one or more delegates to represent American Pedagogy and Science thereat, at some convenient time and place in central Europe.

In like manner the Permanent Secretary is hereby authorized to acknowledge, on behalf of this Association, receipt of such invitation for a like purpose emanating from any government, or department thereof, Institution of Learning, Technical Science, Chamber of Commerce or Finance, Telegraphic or Transportation Bureau, Postal Union or Academy of Arts and Letters, and to pledge the further attention of this Council to the same.

GEOLOGY AND GEOGRAPHY AT THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

PROFESSOR I. C. WHITE, Chairman of the Section, being in attendance upon the International Geological Congress in Russia, the Council filled the vacancy by the election of Professor E. W. Claypole, who read Professor White's address and presided over the meetings of the Section.

After the presentation of the vice-presidential address, the following papers were read:

1. 'The Geological Age and Fauna of the Huerfano Basin, in Southern Colorado,' by Professor H. F. Osborn, New York. The author reviewed the work of R. C. Hills, and concluded from recent field work that the Huerfano Lake deposits are from 800–1000 thick, consisting of upper beds equivalent to Bridger, and lower beds equivalent to Wind River and Wasatch. Below them is an unconformable series, probably Cretaceous. The distribution of deposits indicates a different extension of the lake from that given by Hills. Brief reference was made to the fossils found.

2. 'Lake Chicago and the Chicago Outlet,' by Frank Leverett, Denmark, Iowa. The paper discussed, in detail and with abundant data, the beaches and outlet of Lake Chicago, a glacial lake having southward discharge from the southern end of Lake Michigan basin, through the Des Plaines and Illinois rivers to the Mississippi.

3. 'Some Features of the Recent Geology Around Detroit,' by Frank B. Taylor, Fort Wayne, Ind. Detroit is built on moraines deposited under 200 feet of water. While the ice front was here the western half of Erie basin was filled by a glacial lake. This gives a very smooth surface contour. Shore lines and beaches are well developed. The lower courses of old tributaries of Detroit river are drowned. Streams two miles long have deep estuaries, much deeper than they could erode under present conditions, *e. g.*, Rouge River and Baby Creek. Rouge River, four miles above its mouth, has an average mid-stream depth of from 20 to 30 feet, four times deeper than would be expected from the stream's own erosion. The same is true of the St. Clair tributaries. The succession of events has been as follows: The rivers first flowed as now, but slightly higher. Then, while the upper lakes drained to the Ottawa, abandoning the St. Clair and Detroit Rivers, the streams were cutting to a base level from 25 to 30 feet lower than present river surface. Finally, a northeast uplift established existing conditions

and the refilled Detroit and St. Clair backed up into the deepened tributaries. This confirms the previously supposed temporary drainage of the upper lakes to the Ottawa.

4. 'The Lower Abandoned Beaches of Southeastern Michigan,' by Frank B. Taylor, Fort Wayne, Ind. The paper described the characteristic features, altitudes and deformations of the beaches, and showed that there are at least four important beaches at the south end of Lake Huron, below the Forest Beach of Lake Warren. Two of them, the Elkton and Algonquin, probably extend as far south as Detroit, though not yet traced to this place. The Nipissing beach is supposed to pass under Lake Huron at the south end.

5. 'Recent Earth Movement in the Great Lake Region,' by G. K. Gilbert, Washington, D. C. A comparison of gauge records and bench marks, representing a period of about twenty years, shows that, in the lake region, the land is being tilted from northeast to southwest. The rate is such that of two points one hundred miles apart the northern rises five inches with reference to the southern, in a century. At Chicago the mean lake level is rising at the rate of one inch in ten years. On account of the slight elevation of the divide between Lake Michigan and the Illinois River, a comparatively small tilting of the region will establish an outlet in this direction. It is estimated that, in about three thousand years, all of the upper lakes will discharge into the Illinois River, the current of the Detroit and St. Clair Rivers will be reversed, carrying the water of Lake Erie into Lake Huron, and the Niagara River will run dry.

6. 'A Supplementary Hypothesis of the Origin of the Loess of the Mississippi Valley,' by Professor T. C. Chamberlin, Chicago, Ill. The paper opens by a statement of two great features of the distribution of the loess of the Mississippi Valley which are significant of its origin: (1) The loess is distributed along the leading valleys; (2) it is distributed along the border of the former ice sheet at the stage known as Iowan. These two features indicate the relationship of the loess to the great drainage valleys and to the ice sheet. Nevertheless, the vertical distribution of the loess and the presence of land shells offer great difficulties in the way of accepting the pure aqueous theory. After sketching these difficulties the paper proceeds to offer a hypothesis, which divides the honors between the aqueous and the Eolian agencies. Recognizing the strength of the arguments in favor of a glacio-fluvial origin, it postulates the limitation of the aqueous loess to the lower levels and assumes that the oscillations in the flood stages gave rise to broad, exposed flats, which when dry would be swept by the winds and the dust derived, carried to and lodged upon the uplands, giving rise to an eolian phase of the loess. The paper proceeds to discuss the necessary accommodation between the extent of the aqueous and the fluvial depositions and to compare the combined hypothesis presented with that of Richtofen.

7. 'An Account of the Researches relating to the Great Lakes,' by Dr. J. W. Spencer, Washington, D. C. The author presented an exhaustive review of the gradual development of our knowledge of the Great Lakes, stating the various opinions that have been, and are now, held in regard to their origin, changes and probable future. Being in itself largely a summary, the paper scarcely admits of condensation to the limits of a brief abstract.

8. 'Changes of Level in the Glacial Formations of the Alps,' by Professor Albrecht Penck, Vienna, Austria. The deposits belonging to the glacial period of the Alps must, as to their origin, be divided into true moraine and fluvio-glacial. The moraine deposits occur everywhere where glaciers

have existed, and are not confined to certain levels. The fluvio-glacial gravels, as river deposits, must have had originally a slope in the direction in which the river flowed. This slope has been in some places destroyed by earth movements. This can be shown in the best way by following the oldest of the three fluvio-glacial deposits, the high-level gravel. It formed originally an extensive covering of the low ground of the north Alpine Piedmont region, sloping to the north. Now it forms a series of very flat folds which run parallel to the foot of the western Alps. These folds can be followed from the mouth of the Aar into the Rhine, and from the mouth of the Lech into the Danube, a distance of 250 miles.

The earth movements of the glacial period in the Alps are of a different type from those about the grand American lakes. The American belong to a warping of the earth's crust, which is independent of structural lines; the sub-Alpine shows that the folding of the Alpine system was still going on in early glacial times in the foreland. Whether or not this folding was connected, as Heim assumes, with a bodily sinking of a whole mountain chain, could not be ascertained.

9. 'A Suggestion in Regard to the Theory of Volcanoes,' by Professor W. N. Rice, Middletown, Conn. The distribution of volcanoes gives a clue to their cause. As a generalization, it may be stated that volcanoes occur in localities where there has been recent elevation. Assuming the interior of the earth to be potentially liquid, relief of pressure by crustal uplift might cause fusion, the fused material finding exit by fissures produced during the movement. This idea has been suggested before, but seems deserving of the more explicit formulation presented in this paper. To the objection that contemporaneous sheets of igneous rocks occur in thick masses of sediment, indicating subsidence, it may be answered either that igneous rocks come from adjacent rising areas or that they point to oscillation of movement, progressive subsidence being interrupted by epochs of elevation.

10. 'The Ores and Minerals of Cripple Creek,' by H. P. Parmelee, Charlevoix, Mich. After a short review of the rocks and ores of the region, the important minerals were mentioned, and some described in detail. Specimens of several species were shown, among them a very perfect crystal of calaverite.

11. 'Observations on the Genus Barrettia,' by Professor R. P. Whitfield, New York. The author referred to the original discovery of the fossils and description of the genus by S. P. Woodward, with its reference to the Rudistidæ; he then pointed out several peculiar features of the fossils not noticed in the original description and called attention to their strong resemblance to cup corals, and their general radiate structure. The description was based upon a large collection of specimens obtained from Jamaica, W. I.

12. 'Ice Jams and what they Accomplish,' by Dr. M. A. Veeder, Lyons, N. Y. The paper dealt with the effect of ice forced through river channels, partly floated and partly grounded on the land through choking of the outlets of lakes. The channeling of rock surfaces in the St. Lawrence valley and the formation of parallel ridges in Salina marls and shales were ascribed to this action.

13. 'The Lower Carboniferous of Huron County, Michigan,' by Dr. A. C. Lane, Houghton, Mich. This paper, read by Mr. W. F. Cooper, described the Bayport limestone, the Michigan salt group and the Marshall series, as exposed along the 'Thumb' of the Lower Peninsula. The localities were arranged in their proper position in the geological column, and it was shown that the rocks have a greater

thickness than was formerly supposed. Preglacial stream valleys were also treated.

In the absence of the authors the following papers were read by title:

14. 'Progress of Hydrographic Investigations by the United States Geological Survey,' by F. H. Newell, Washington, D. C.

15. 'Stylolites,' by Professor T. C. Hopkins, State College, Pennsylvania.

Tuesday was given to the Geological Society, and Wednesday afternoon the Section met with Section H, joining in the discussion of the human relics found in the Trenton gravel.

C. H. SMYTH, JR.

HAMILTON COLLEGE.

GEOLOGICAL SOCIETY OF AMERICA.

THE ninth summer meeting of the Society was held at Detroit, August 10th, under the presidency of Professor Edward Orton.

The Secretary announced the election of nine fellows.

The following papers were read:

1. 'The Granite Mountain Area of Burnet County, Texas,' by F. W. Simonds. The area described embraces about fifty square miles, from which the overlying strata have been removed, and the granite reduced to a plain, except at Granite Mountain and Johnson's Rock, which rise about one hundred feet above the general surface. The granite is a biotite granite and is quarried on a considerable scale, affording an excellent building material. After reviewing the opinions of Walcott, Hill and Comstock in regard to the age of the granite, the author concluded that the intrusion accompanied post-Carboniferous disturbances, and may have been as late as Cretaceous.

2. 'Stratigraphy and Structure of the Puget Group, Washington,' by Bailey Willis. The Eocene and Miocene strata adjacent to Seattle and Tacoma are folded and faulted in a manner closely analogous to that of the Appalachian region, but the compressing force acted from the west instead of the east. The fresh-water Eocene is much like the eastern Carboniferous, consisting of arkose sandstones and clay shales containing iron carbonate nodules, with beds of coal or black shale every one hundred, to one hundred and thirty, feet. The total thickness exceeds eight thousand feet. When slightly disturbed, the coal is lignite, but as the amount of disturbance increases there is a passage into steam coal with cubical fracture, and, finally, into coking coals. The coals, being planes of easy slipping, have greatly affected the folding, and have themselves often been crushed to powder.

3. 'The Loess as a Land Deposit,' by J. A. Udden. Observation indicates that the air is not depositing dust in sufficient quantities to build the loess, which spreads over such great areas, at elevations ranging from 300 to 3,000 feet. But the amount deposited varies greatly and may have been much larger in early post-glacial times. The loess closely resembles undoubted wind-blown deposits, while in its uniformity and prevailing lack of bedding plains it is quite different from most aqueous sediments. On the whole, the actual phenomena exhibited by the loess seem to accord better with the hypothesis of Eolian origin than with any other.

4. 'Analogy between Declivities of Land and Submarine Valleys,' by J. W. Spencer. With the aid of diagrams, the author pointed out the close resemblance existing between subaërial and submarine valleys, particularly in the Antillean region. He concluded that such similarity of topography must indicate a common origin, and that the present sea bottom must be a submerged land surface. This shows a sinking of ten to fifteen thousand feet in the Antillean basin, which was probably compensated by an elevation in the region of Mexico.

5. 'Great Changes of Level in Mexico, and the Inter-Oceanic Connections,' by J. W. Spencer. The geological basement of Mexico is a post-Cretaceous base level, out of which rise the higher mountains. A deep-water formation of Mio-Pliocene age rests unconformably upon the Cretaceous. These rocks, by their distribution, point to a Pliocene submergence, with 'canals' or straits connecting the Pacific and Gulf waters. This conclusion is further substantiated by the similarity of the shallow water faunas on the opposite sides of the isthmus, the deeper water forms being quite unlike. This connection was broken by a recent, almost modern, elevation, amounting, in some places, to 8,000 feet.

6. 'The Origin of the Gorge of the Whirlpool Rapids of Niagara,' by F. B. Taylor. From the falls to the cantilever bridge the Niagara gorge is broad. At the latter point it suddenly narrows, and the diminished width continues to within eighty rods of the whirlpool. From here to Lewiston it is wide again. The author ascribed the formation of the broad upper and lower gorges to the action of the great cataract carrying the entire discharge of the upper lakes. The narrow gorge of the whirlpool rapids was referred to a smaller cataract, when the three upper lakes were draining through the Nipissing into the Ottawa. Thus, the latter gorge, being cut by a comparatively small river, must have required for its formation a long time, probably not less than 20,000 to 25,000 years. This considerable period must, therefore, be reckoned with in estimating post-glacial time.

7. 'The Glacial Drainage of the Simcoe Area in Ontario,' by F. B. Taylor. In this paper the author gave reasons for believing that during a period when the Nipissing outlet was closed, a drainage channel was established from Georgian Bay through the River Trent.

8. 'Exposures near Detroit of Helderberg Limestone, and Associated Gypsum Salt, and Sandstone,' by W. H. Sherzer. The highest rocks exposed in southeastern Michigan are Upper Helderberg, nearly or quite equivalent to Corniferous. They are very pure limestones with chert beds, and have a thickness of 100–160 feet. Beneath them is a series equivalent to the Water-lime, chiefly drab dolomites, sometimes oölitic. Some distance below the top of the Water-line is intercalated a bed of white sand, almost pure quartz, many of whose grains show secondary enlargment. Extending to a depth of over 2,000 feet beneath Detroit is a series of beds of gypsum and rock salt, the latter aggregating a thickness of five hundred feet in three beds. Thus, Detroit possesses, in almost unlimited quantities, the pure limestone and salt which are the raw materials of the soda ash and caustic soda industry.

The following papers were read by title:

9. 'Notes on the Geology of the Lower Peninsula of Michigan,' by A. C. Lane.

10. 'The Nomenclature of the Carboniferous Formations,' by R. T. Hill.

11. 'Ice-transported Boulders in Coal Seams,' by E. Orton.

12. 'Clay Veins Vertically Intersecting Coal Measures,' by W. S. Gresley.

Hamilton College.

REGENERATION IN OLIGOCHAETE WORMS.

Professor T. H. Morgan, of Bryn Mawr, has made the following summary of recent studies upon regeneration in worms:*

1. Pieces of the anterior end of Allolobophora fœtida containing less than thirteen segments rarely, if ever, regenerate posteriorly, yet such pieces can regenerate very quickly anterior segments if these are cut off. The result shows that the lack of power of the anterior pieces to regenerate

* Archiv für Entwickelungsmechanik, V. Band, 3 Heft.

posteriorly does not depend, directly, on the size of the piece. 2. Anterior ends containing from thirteen (?) to thirty segments sometimes regenerate posteriorly, but only after a long time and in general, the shorter the piece (*i. e.*, the nearer the cut to the anterior end) the longer the interval before it begins to regenerate, and the fewer the pieces that regenerate at all. 3. Similarly very short posterior pieces do not regenerate anteriorly; longer pieces from the posterior end regenerate occasionally, but only after a long interval of time. In general the shorter the posterior piece the longer the time before the piece begins to regenerate anteriorly. 4. The experiments show that Weismann's hypothesis of latent cells is insufficient to explain the phenomena of regeneration, because it can not account for the delay in regeneration of a lost part under the circumstances given above. 5. Short pieces from the middle of the worm sometimes regenerate both anteriorly and posteriorly. 6. If a worm be cut in two pieces and then the anterior end be cut off again from the anterior piece, the middle piece will regenerate posteriorly at the same rate and time as though the anterior end had not been cut off. 7. If posterior ends of two worms be sewed together and if then one of the ends has a part cut off, the part that regenerates is like the part removed; *i. e.*, a new posterior end, and not a new head regenerates.

The power to regenerate is, in some cases, of the greatest use to an animal since it enables the animal, if injured, to reproduce the lost parts. It is, therefore, surprising to find the phenomenon of regeneration almost entirely neglected by the advocates of the theory of natural selection. Darwin scarcely alludes to the matter and most of his followers make little or no reference to the subject. Weismann, however, in his recent book on the Germ Plasm has opened up the question. A quotation will serve to show how successfully he has treated the matter from the selectionists' standpoint. "The power of regeneration in any particular part cannot depend only on the conditions which exist as regards the species under consideration; it must also be due to arrangements for regeneration which have been transmitted by the ancestors of the species. Leaving the question aside, and regarding the power of regeneration as merely depending in each individual case on adaptation, we should arrive at some such conclusion as the following: the provision of the cells of a certain part with supplementary determinants for the purposes of regeneration depends primarily on the liability of this part to frequent injury * * * * a useless or almost useless rudimentary part may often be injured or torn off without causing processes of selection to occur which would produce in it a capacity for regeneration." How an infinite number of injuries to a part could ever produce in it a capacity for regeneration is far from clear. Injured animals would be, on the whole, at a disadvantage in the struggle for existence; if some of them have the power to regenerate already they are neither better nor worse off than those that have not been injured. Just how injured animals would ever be able in each generation to obtain an advantage over uninjured animals is by no means self-evident. In my experiments, for instance, I find that only rarely do posterior ends of worms cut in the middle regenerate anteriorly, and even in those cases where this happens the regeneration is almost always imperfect. Does this mean that as yet an insufficient number of these worms have been injured in this way? In the course of time if more worms are injured by accidents, will Allolobophora fœtida acquire a capacity for regenerating the anterior end? Are we to consider seriously this interpretation of the selection theory?

THE SURVEY OF THE FOREST RESERVES.

Professor Chas. D. Walcott, Director tor of the United States Geological Survey, has just returned to Washington after an absence of three months and a-half spent in the field.

In the course of his journeys Mr. Walcott gave a short time to geologic investigation in the Sierras, on his own account, and to attending to the general affairs of the bureau. He was engaged principally, however, in looking after the surveys and investigations of the suspended forest reserves, a work only just entered upon by his bureau, and to start which Congress at the last session made an appropriation of $150,000. This work was started and got under way in July. In connection with this branch of work topographic and subdivision surveys are being made in nine of the forest reserves of the West, the field being divided between two of the topographic divisions or sections of the Survey. Mr. R. U. Goode, of the Pacific Section, is making surveys in the Bitterroot, the Priest River and the Washington reserves, while Mr. Douglas, of the Rocky Mountain Section, is surveying the Lewis and Clarke and the Flathead reserves of Montana, the Big Horn and Téton Reserves of Wyoming and the Uinta Reserve of Utah. Before the season closes Mr. Goode will also work in the San Jacinto Reserve of southern California, sending some of his parties into that area when they are driven by bad weather out of the more northern reserves.

Data on which to base definite statements of the results of the surveying work of the season are not yet available. Preceding the topographic work proper triangular and spirit-level lines are being run, except in the higher and more rugged regions, where there are no roads and trails. The subdivision surveys are being made in the same manner as the subdivision surveys in Indian Territory. Another feature is the outlining by the surveyors, in the course of their other work, of all wooded and forested areas, and another is the erection, at suitable intervals, of permanent bench marks, to mark the elevation above sea level. There are from one to three parties in each reserve. It is yet too early for definite statements of the results of the season's work, but such data as are at hand indicate that the surveys have progressed satisfactorily, considering the lateness of the start, the rugged character of much of the country traversed, etc. In the Washington and Flathead Reserves work was discontinued at the close of September on account of snow and otherwise unfavorable weather, but at last reports it was still going on in all other localities.

The topographic maps which will result from the topographic surveys will be on the scale of two miles to the inch with 100 foot contour intervals. These will serve as base maps for the representation of forestry details, agricultural and mineral lands, etc. The subdivision surveys will enable the demarkation of tracts of land for agriculture, for minerals and for timber.

The general economic investigation of the reserves is under the charge of Mr. Henry Gannett, who is assisted by seven forestry experts. The reserves, and the experts assigned to each, are the Black Hills Reserve, H. S. Graves ; the Big Horn Reserve, F. E. Town; the Priest River Reserve and the eastern part of Bitterroot Reserve, John B. Leiberg; the eastern portion of Washington Reserve, W. Y. Steele and M. W. Gorman ; the western portion of the Washington Reserve, H. B. Ayers, and the Téton Reserve, Dr. T. S. Brandegee. Work was begun in these several reserves at various dates between July 1st and August 15th. It has since progressed satisfactorily in all the reserves, according to Mr. Gannett, who has just returned to Washington and made his first report of the season. The first area to be completed, Mr. Gannett says, is the

Priest River Reserve, which was finished about the end of July; the second the Téton, finished about the middle of September. The Big Horn Reserve is practically completed at this date. Work in the other areas is still in progress, or was when Mr. Gannett reported.

The information obtained by Mr. Gannett's division touching these reserves relates to the condition, value and character of the timber; the density of undergrowth; the prevalence of fires in past times; the extent of cutting; the location and extent of lands more valuable for other purposes than for timber; the amount of settlement within the reserves, and the demand for timbers in their neighborhood. It is expected that the results obtained will be of value to the government in delimiting the boundaries of the reserves and in their future administration.

WASHINGTON, October 20, 1897.

CURRENT NOTES ON ANTHROPOLOGY.

MAYA DAY SYMBOLS.

IN the 'Sixteenth Annual Report of the Bureau of American Ethnology,' Professor Cyrus Thomas has an elaborate article of sixty pages on the day symbols of the Maya year. In this study he follows the list of days as given by most authorities, beginning with *imix.* After quoting the names assigned them in five of the seven languages where this calendar was in use, he comments upon the meaning and relationship of the various terms. He departs in frequent instances from the opinions of earlier writers, but in the main agrees that in a general way there exists a connection between the terms used to designate any one day.

He has taken pains to point out in several passages some similarities in the meaning of the day-names to superstitions found among the Polynesian islanders. These are somewhat striking, but scarcely so much so as the similarities long ago pointed out between the Mexican and certain Eastern Asiatic calendars by Alexander von Humboldt. They are such as may be found the world over when we compare early attempts to measure time for religious or divinatory purposes.

The paper is abundantly illustrated, and will prove a useful work of reference to the student of Mayan hieroglyphs.

THE VIKING CLUB.

THE voyages of the Northmen to America excite an interest in their ancient memorials among American scholars. All such will welcome the periodical issued by the Viking Club under the name of *The Saga-book.* Its aim is to concentrate the study of Norse mythology, history and literature. Especial attention is given to ancient inscriptions on stone or other material exhibiting the runic and symbolic figures of the early script. The extension of the Norsemen through Scotland and Ireland was accompanied by a large amalgamation of Celtic elements. It has been shown that this reached by transmission to Iceland, where we find a considerable number of ancient Celtic names.

The *Saga-book* is handsomely printed and illustrated and may be bought of the publisher, David Nutt, London. The club itself is founded as a social and literary society for all interested in the North and its literature and antiquities. Meetings are held in London from November to June. It aims to found a library, to present and discuss papers on Northern antiquities, to encourage the publication of documents, arrange for exhibitions, etc. The subscription is ten shillings yearly, which entitles to a copy of the 'Proceedings.' Applications may be sent, care of the publisher, 270 Strand.

UNIVERSITY OF PENNSYLVANIA.

BOTANICAL NOTES.

A MODEL NATURAL HISTORY SURVEY BULLETIN.

A FEW years ago the State Botanist of Minnesota began publishing botanical papers bearing upon the botany of his State in periodical bulletins under the name of 'Minnesota Botanical Studies.' These have attracted wide attention as well from the matter which they contained as the manner of their publication. The State law under which the natural history survey is conducted provides for the immediate publication of scientific contributions in the form of bulletins, in advance of the annual report, and this wise provision has enabled the State Botanist to conduct the unique publication referred to above. The first number was issued in January, 1894, since which ten more numbers have appeared, covering 1,043 pages, accompanied by eighty plates, and including fifty botanical papers. The wide range of these papers may be seen from the following synopsis :

	No. of Papers.
Morphology	1
Histology	1
Physiology	14
Phytogeography	7
Algæ	5
Fungi	4
Lichens	3
Liverworts	1
Mosses	6
Flowering Plants	7
Slime Moulds	1

Among the titles are the following: 'On the occurrence of Sphagnum atolls in Central Minnesota,' 'A revision of the Mucoraceæ with especial reference to species reported from North America,' 'A preliminary list of the mosses of Minnesota,' 'Titles of literature concerning the fixation of free nitrogen by plants,' 'A contribution to the bibliography of American Algæ,' 'On the distribution of the North American Helvellales,' 'A rearrangement of North American Hyphomycetes,' 'Contributions to a knowledge of the lichens of Minnesota,' 'The alkaloids of *Veratrum.*'

A comparison of the foregoing titles and subjects with those which commonly fill the pages of the publications of other natural history surveys justifies us in regarding this bulletin as a model which might profitably be followed in other States.

THE USEFUL FIBER PLANTS OF THE WORLD.

THE United States Department of Agriculture has recently issued a most useful nd interesting descriptive catalogue of the useful fiber plants of the world. It was compiled by the well-known statistician, Charles R. Dodge, and is the result of many years of labor. It includes 1,018 fibers alphabetically arranged, and illustrated by 102 cuts and twelve half-tone plates.

In the treatment of each fiber a brief description is given of the plant from which it is derived, and this is followed by a description of the fiber and the operations by which it is prepared for use. In cases of the more important fibers further details are given as to cultivation, preparation for the market, commercial statistics, etc.

The introductory chapter includes some interesting sections, that upon the principal fibers used commercially in the United States being especially noteworthy. From it we learn that about thirty species are used in this country, and that with the exception of the Cabbage Palmetto (*Sabal palmetto*), the Saw Palmetto (*Serenoa serrulata*) and Spanish Moss (*Tillandsia usneoides*), we are still more or less dependent upon foreign growers for our supply. Thus of the more common fibers, flax is imported from Belgium, Russia, Holland, Italy, Great Britain and Canada ; hemp, from Russia, France, Belgium, Germany, Austria-Hungary, Italy and the Netherlands ; jute, from India ; cotton, from Egypt and Peru ; raffia, (used for tie bands), from Africa; sisal

hemp, from Yucatan; manilla hemp, from the Philippine Islands, etc.

Two classifications of fibers are presented, structural and economic.

The first is as follows:

A. FIBRO-VASCULAR STRUCTURE.

1. *Bast fibers* (of dicotyledons).
2. *Woody fibers* (of dicotyledons), from (*a*) twigs and small stems, used entire, (*b*) roots, (*c*) trunks split or cut into layers or splints, (*d*) trunks ground into pulp.
3. *Structural fibers* from (*a*) the isolated fibro-vascular bundles of the leaves and leaf stalks of monocotyledons, (*b*) the whole stems, roots or leaves of monocotyledons, (*c*) the fibrous portions of the leaves or fruits of certain dicotyledons.

B. SIMPLE CELLULAR STRUCTURE.

4. *Surface fibers*, including (*a*) hairs on seeds, (*b*) hairs from stem surfaces, and (*c*) epidermal strips from leaves, as of certain palms.
5. *Pseudo-fibers*, including (*a*) certain mosses, as species of sphagnum, (*b*) certain seaweeds used for packing, (*c*) certain seaweeds for cordage, (*d*) the mycelium of certain fungi.

Economically, fibers are classified as follows:

A. *Spinning fibers*, including (1) fabric fibers, (2) netting fibers, (3) cordage fibers.

B. *Tie material.*

C. *Natural textures*, including (1) tree basts with tough interlacing fibers, as in the 'lace barks,' (2) ribbon or layer basts, (3) interlacing structural fibers or sheaths, as cocoanut sheaths.

D. *Brush fibers*, including (1) prepared fibers from isolated fibro-vascular bundles, (2) fibers from roots, flower pedicels, etc., (3) twigs and splints.

E. *Plaiting and rough weaving fibers*, including those used for (1) making hats, sandals, etc., (2) matting, thatching, etc., (3) baskets, (4) chair-bottoms, etc.

F. *Various forms of filling*, as (1) stuffing for chairs, cushions, mattresses, etc., (2) caulking, (3) stiffening, *e. g.*, in the manufacture of 'staff,' (4) packing.

G. *Paper material*, for making (1) textile papers, (2) bast papers, (3) palm papers, (4) bamboo and grass papers, (5) wood-pulp papers.

CHARLES E. BESSEY.
THE UNIVERSITY OF NEBRASKA.

SCIENTIFIC NOTES AND NEWS.

REPORT OF THE SECRETARY OF AGRICULTURE.

THE Secretary of Agriculture has presented to the President his report reviewing the work of the Department for the past year. The conduct of the Department under Secretary Wilson has greatly advanced the economic and scientific study of agriculture and the conditions on which agriculture depends, and the recommendations of his report will consequently carry much weight.

Mr. Wilson proposes that agents for the Department should be stationed at each of the important American legations abroad for the collection of information of interest to American farmers. The Department is endeavoring to get information from foreign countries with which to compete in the markets of the world regarding crops and prices, and is also taking steps to ascertain what crops are grown on different thermal lines, so that seeds and plants may intelligently be brought to this country to assist in the diversification of our crops and add to their variety. There is a necessity for American agents, educated in agricultural science, in every foreign country to which are sent reports.

Mr. Wilson recommends an increase in the appropriations in aid of the Bureau of Animal Industry, of the Weather Bureau and of the publication offices. He thinks the Department should be enabled to place the results of important operations at agricultural colleges before the entire country, so that the farmers of each State may benefit from the work done in

other States. The present method of securing crop reports is criticised, and the employment of a statistical agent in each State with paid reporters is recommended.

Mr. Wilson not only believes that the exports from America can be greatly increased, but that nearly all the imported agricultural products, valued at $400,000,000, could be and should be produced at home.

THE GEOLOGICAL SURVEY OF WEST VIRGINIA.

AT the last session of the Legislature of West Virginia an act was passed establishing a State Geological and Economic Survey, to be under the direction of a commission consisting of the Governor, State Treasurer, President of the State University, Director of the Agricultural Experiment Station, and President of the State Board of Agriculture. Three thousand dollars a year was appropriated to carry on the work. The act is similar to that establishing the Geological Survey of Maryland, in which the corporation of the Johns Hopkins University was secured and the Survey inaugurated in a manner so promising for science and economic usefulness.

The commission of the West Virginia Survey met in Wheeling last month and organized, electing Governor Geo. W. Atkinson President; Mr. M. A. Kendall (State Treasurer), Treasurer; Professor T. C. Atkeson (President of the State Board of Agriculture), Secretary; Mr. J. H. Stewart (Director of the Experiment Station), Superintendent of the Department of Economic Biology; and President Jerome H. Raymond (West Virginia University), Executive General Officer. Dr. I. C. White was elected Superintendent of the Survey. He is in Europe now, and it is not yet known whether he will accept, but he will return soon, and then the real work of the Survey will begin. Professor S. B. Brown, professor of geology in the University, was elected First Assistant Geologist and Curator of the Collections. Professor J. L. Johnston, professor of civil engineering, has been appointed Assistant Geologist, with the special duty of locating the meridian lines of each of the county seats of the State. The headquarters of the Survey are at the West Virginia University, Morgantown.

THE NEW YORK ZOOLOGICAL PARK.

A LETTER from Mr. William Hornaday, Director of the New York Zoological Park, published in the *Critic*, calls attention to a fact perhaps not known to those who have objected to increasing the attraction of the park lands north of the Harlem River by using a small part of them for botanical and zoological gardens. Mr. Hornaday writes:

"The Hon. W. W. Niles, who was a member of the Commission which (in 1884) selected the 4000 acres of farm lands in the Annexed District, now included in the four great parks, declares most positively that in determining the total area of land to be condemned and purchased by the city the Commissioners made the area as large as it is in order to provide abundant room for the large zoological and botanical gardens which they felt sure would soon be established by the city. In other words, it was the deliberate *expectation and intention* of the Commissioners that both of the institutions now complained of should find homes on some of the lands then acquired. The Commissioners very wisely did not attempt to assign sites for the zoological and botanical gardens. In choosing a home for the former, the Zoological Society naturally inferred that the site which would be the most accessible to the public, and also immeasurably the best for the animals, was the proper one to choose. There are 3,500 acres of public parks in the Annexed District, untouched by the two scientific gardens, or five and one-half square miles. Is not that enough? Of the 261 acres alloted to the Zoological Park, the collections will be located on the least attractive portion; fully one-half of the total area (*all* of the picturesque portion) has been set aside as pleasure grounds, only."

THE INTERNATIONAL LEPROSY CONFERENCE.

AT the conclusion of the recent International Leprosy Conference at Berlin the secretaries drew up a summary of the results in English, German and French, intended especially for the governments who had sent delegates. The conclusions are as follows:

1. As might be expected, a considerable portion of the proceedings has been in connection with the bacillus of leprosy, which the Confer-

ence accepts as the virus of the disease, and which has been now known to the scientific world for upwards of twenty-five years through the important discovery of Hansen and the able investigations of Neisser.

2. The conditions under which the bacillus grows and develops are still unknown, as well as the way of its invasion into the human system; but from the discussions at the Conference it seems probable that a unanimity of opinion will soon prevail with regard to the modes of its dissemination throughout the body.

3. Very interesting observations have been brought forward concerning the large quantities of bacilli which are eliminated from the bodies of lepers through the skin and the buccal and nasal mucous membranes. It is desired that these observations be confirmed where opportunities occur. This question is important to those who are entrusted with the care of the public health, as we have to acknowledge that leprosy is a contagious disease.

4. Every leper is a danger to his surroundings, the risk varying with the nature and extent of his relations therewith and with the existing sanitary conditions. Although in the poorer classes the leper is especially a source of danger to his family and fellow workers, it cannot be denied that cases frequently occur also in the higher social circles.

5. The theory of the heredity of leprosy has lost ground in comparison with the now generally accepted opinion of its contagiousness.

6. The treatment of leprosy up to the present time has only had palliative results. Serum-therapy, so far, cannot be said to have been successful.

7. In view of the virtual incurability of leprosy and the serious and detrimental effects which its existence in a community causes, and considering the good results which have followed the adoption of legal measures of isolation in Norway, the Leprosy Conference, as a logical issue of the theory that the disease is contagious, has adopted the following resolution, proposed by Dr. Hansen and amended by Professor Besnier: (*a*) In countries where leprosy forms *foci* or has a great extension, isolation furnishes the best means of preventing the spread of the disease. (*b*) The system of obligatory notification, observation and isolation as carried out in Norway is recommended to all nations with local self-government and a sufficient number of physicians. (*c*) It must be left to the administrative authorities, after consultation with the medical authorities, to take such special measures as are applicable to the special social conditions of the districts.

GENERAL.

MR. HENRY S. PRITCHETT, Ph.D. (Munich), professor of physics and astronomy in Washington University, St. Louis, has been appointed by the President, Superintendent of the Coast and Geodetic Survey in the place of Gen. W. W. Duffield, resigned. Professor Pritchett was from 1878 to 1880 Assistant Astronomer at the Naval Observatory, Washington. He has engaged in work for the Survey in China and Japan as well as in the United States. We regret to notice the statement that Professor Pritchett is a Republican in politics, but hope that this is a mere accident and does not mean that the head of the Survey is liable to be changed every four years. There is every reason to believe that the Survey will now be conducted with the greatest efficiency and will contribute largely to the solution of the important practical and scientific problems with which it is charged.

IT is announced that the conference of delegates from the United States, Russia and Japan in regard to the seal fisheries has resulted in an agreement recommending the material limitation or complete suspension of pelagic sealing. Professor D'Arcy Thompson is now in Washington and it is expected that Mr. Macoun, the Canadian Minister of Marine, will shortly arrive, and that the conference between the United States, Great Britain and Canada will soon be held.

PROFESSOR F. F. MARTENS, professor of international law in the University of St. Petersburg, has been chosen an arbitrator in the question of the Venezuela boundary.

DR. H. HICKS, President of the Geological Society, London, has been awarded the jubilee medal established in commemoration of the sixtieth anniversary of the Queen's reign.

DR. EDMUND DRECHSEL, professor of physio-

logical and pathological chemistry and of pharmacology in the University of Berne, died on September 22d at Naples, where he was working at the zoological station on the chemistry of invertebrates. Drechsel was born at Leipzig in 1843 and was assistant to Kolbe, then professor of chemistry, and to Ludwig, then professor of physiology in that University. He was made associate professor at Leipzig in 1878 and was called to Berne in 1880. Physiological chemistry has recently suffered most serious losses in the deaths of Hoppe-Seyler, Baumann, Heidenhain and Drechsel.

DR. ALEXANDER MILTON ROSS died at Montreal on October 27th. He had made extensive collections of the fauna and flora of Canada and was the author of 'Birds of Canada' (1872); 'Butterflies and Moths of Canada' (1873); 'Flora of Canada' (1873); 'Forest Trees of Canada' (1874); 'Ferns and Wild Flowers of Canada' (1877); and 'Mammals, Reptiles and Fresh-water Fishes of Canada' (1878).

SIR PETER LE PAGE RENOUF, the eminent Egyptologist, died in London about the middle of October at the age of seventy-four years. He was the keeper of the Egyptian and Assyrian antiquities of the British Museum from 1885 to 1891, and was the author of several important publications, including the Hibbert lectures on 'The Religion of Ancient Egypt' (1897), and an edition of the 'Papyrus of Ani.'

THE following deaths are also announced: Dr. Leopold Auerbach, assistant professor of physiology in the University of Berlin; Dr. Mietschke, the German naturalist and entomologist; Dr. Hjalmar Heiberz, professor of pathological anatomy in the University of Christiania, and Dr. R. Branchat, professor of hygiene in the Medical Faculty of Granada.

IT is said that the Norwegian government will not only allow Captain Sverdrup the use of the 'Fram,' but will give him $50,000 for an outfit. According to *Petermann's Mitteilungen* Captain Sverdrup had given up the intention of making investigations between Spitzbergen and Greenland, and it had been decided that he should proceed up Baffin Bay and Smith Sound to the part of the Arctic ocean north of Greenland, which is the region Lieutenant Peary had previously announced his intention to explore.

A CABLEGRAM from Christiania states that the government has instructed the Governor of the Province of Tromsöe, the most northern province of Norway, to charter a steamer at the expense of the state, to provision it for six months and to send out a relief expedition for Herr Andrée, the aëronaut, who ascended in his balloon, the 'Eagle,' on July 11th. The relief steamer will start in three days' time from Tromsöe, and will proceed to Spitzbergen.

THE Imperial Russian Geographical Society will send at once an expedition, under the direction of M. Dmitrieff, to Abyssinia for anthropological research.

THE Austrian steamship 'Pola,' Captain Paul von Pott, has again gone to the Red Sea for scientific explorations, and will this year cover the ground between Dschedda and Aden. Dr. Franz Steindachner, the eminent ichthyologist, has charge of the zoological work, and explorations will also be made in physical oceanography.

PROFESSOR CHARLES BURCKHALTER, of Chabot Observatory, Oakland, Cal, has left for Hong Kong, and will proceed to India with his instruments for the purpose of observing and photographing the approaching total solar eclipse of the sun.

PRINCE PETER ALEXEIEVITCH KRAPOTKIN, the eminent Russian man of science, President of the Imperial Geographic Society, lectured in Washington on October 22d, before the National Geographic Society, on Russia and Siberia, dwelling at length on the geography of Siberia, which he compared with that of North America.

PROFESSOR ELLIOTT has been nominated for the presidency of the London Mathematical Society.

THE Astronomical Society of France held on October 6th its first meeting for the season. The President, M. Cornu, opened the session with an account of the astrophysical work of Fizeau. MM. Callandreau and Moye presented papers on the trajectories of comets and meteors.

THE Agnew Memorial Pavilion of the Hospital

of the University of Pennsylvania was opened on October 15th. It has been erected at a cost of $150,000, and in addition to 120 beds, dispensary rooms, etc., contains three ampitheaters, one with a seating capacity of 270.

MR. WILLIAM C. TODD, of Atkinson, N. H., has given the Boston Public Library $50,000, the income of which is to be used for the purchasing of newspapers.

THERE has been held at Sydney, New South Wales, during the present summer, an electrical exhibition at which engineering machinery and scientific apparatus were well represented. A large number of exhibits were sent from America and Great Britain.

THE Zoological Park, Washington, has received three young buffaloes purchased from the Allard herd in Montana.

THE Kingsley Laboratory, the new scientific building of the Worcester Academy, was dedicated on October 30th. Addresses were made by President Eliot, of Harvard University; President Hall, of Clark University, and President Mendenhall, of the Worcester Polytechnic Institute. The building is said to be the best equipped for the study of the sciences possessed by any secondary school.

AT a meeting of the Council of the Australasian Association for the Advancement of Science on September 8th the honorary Secretary, Professor A. Liversidge, stated that he had received the titles of the following addresses: Section C—Geology and Mineralogy: Professor Hutton, F.R.S., of New Zealand, upon 'Early Life on the Earth.' Section F—Anthropology and Ethnology: A. W. Howitt, of Melbourne, 'On the Origin of the Aborigines of Tasmania and Australia.' Section I—Sanitary Science and Hygiene: The Hon. Allan Campbell, of Adelaide, 'Australian Sanitation, a Jubilee Retrospect.' Among other papers announced in addition to those we have already noticed are the following bearing upon the natural history of Australasia: For Section C—Geology and Mineralogy: 'Notes on the Physiography of the Parish of St. George, New South Wales,' by E. J. Statham; 'On Some Effects of the Dynamo-Metamorphism in the Omeo District, Victoria,' by A. W. Howitt; 'Metallurgical Methods in Use at Broken Hill,' by G. W. Blakemore; two papers by Mr. J. C. H. Mingaye, on 'Occurrence of Phosphatic Minerals at the Jenolan Caves, with Analyses,' and 'Notes and Analyses of some New Wales Phosphate Minerals.' For Section D—Biology: 'On the Physiology of the Brain of Marsupials,' by Dr. J. F. Cashman; 'Notes on the Fertilization of some North Australian Plants,' by Nicholas Holtze; 'A Few Words about the Flora of the Islands of Torres Straits and the Mainland about Somerset,' and 'Notes on Plants of the Rabbit-infested Country, Bulloo River, Southwest Queensland,' with Photographic Illustrations,' by J. F. Bailey. For Section E—Geography: 'The Earliest Discoveries in New Guinea and Polynesia,' by James MacClymont; 'Gramineæ of Western Australia,' 'Salsolaceæ of Western Australia,' and 'The Supposed Poisonous Plants of Western Australia, by F. Turner.

TWO new museums will be opened at St. Petersburg in connection with the Army Medical Academy, one for psychiatry and one for neurology. The former will include objects illustrating the arrangements of asylums and the pathology of insanity, while the latter will illustrate the anatomy of the nervous system.

A PUBLICATION issued from the French Ministry of Finance gives some very elaborate statistics as to the quantity of wine, beer, cider, and alcohol consumed in the country. From the summary in the London *Times* we learn that the total quantity is 1,575,000,000 gallons, representing about 1½ litres per diem for the whole population of France. Out of the total quantity consumed 967,000,000 gallons are wine, 395,000,000 gallons cider, 202,500,000 gallons beer, and 36,800,000 gallons alcohol. It is scarcely necessary to say that, while the greater quantity of the wine is consumed in the large towns, the cider is nearly all drunk in the country, especially in Normandy and Brittany, and the official statistics give a table showing what is the consumption of wine in the 47 towns with over 30,000 inhabitants. The figures, as might be expected, vary very much, the annual consumption being largest at Boulogne-sur-Seine (59 gallons), Nice (56 gallons) and St. Etienne (54 gallons), while Paris is only 13th

on the list with 45 gallons. In none of the large towns in the South of France does the consumption fall below 30 gallons, but in seven large town in the North (Lille, Boulogne-sur-Mer, Dunkirk, Caen, Calais, Roubaix and Turcoing) it averages only six gallons. Another table gives the consumption of alcohol, and here Rouen, Cherbourg and Le Havre head the list with an annual total of nearly four gallons per head of the population, or more than double the quantity consumed in Paris.

UNIVERSITY AND EDUCATIONAL NEWS.

THE late George M. Pullman has left $1,200,000 for the erection and endowment of a manual training school in the town of Pullman.

THE Ohio Wesleyan University has received a bequest of $35,000 from the late Stephen Watson for the endowment of a professorship.

THE West Virginia University has followed the example of the University of Chicago, and will hereafter hold continuous session, the academic session being divided into four quarters of twelve weeks each with an intervening vacation of one week.

AN increase of forty-two students over last year is reported at Harvard College. The registration is as follows: Seniors, 337; juniors, 383; sophomores, 443; freshmen, 470; specials, 163; total, 1,796.

DR. CHARLES W. DABNEY, recently Assistant Secretary of Agriculture, and special agent in charge of scientific and statistical investigations, Washington, D. C., has been elected President of the University of Tennessee.

DR. ARTHUR ALLIN, of Ohio University, has been appointed professor of psychology and pedagogy in the University of Colorado.

DR. A. W. SHEEN has been appointed demonstrator in anatomy and Mr. S. C. Mahalanobis demonstrator of physiology in the medical department of University College of South Wales, Monmouthshire.

J. GRAHAM KERR, B.A., scholar of Christ's College, Cambridge, has been appointed demonstrator in animal morphology for a period of five years from October 1, 1897, in place of Mr. E. W. MacBride, who had resigned in order to accept the professorship of zoology in McGill University.

THE electors to the professorship of pathology, Cambridge University, will meet for the purpose of proceeding to the election of a professor on Saturday, November 6th. It is expected that Dr. Kanthack will be elected.

DR. HERMANN MUNK has been promoted to a full professorship of physiology at the University of Berlin. Dr. Hettner, of Leipzig, has been appointed assistant professor of geography in the University at Tübingen, and Dr. Max Busch assistant professor of analytical chemistry and chemical technology in the University at Erlangen.

THE annual report of President Schurman, of Cornell University, is the first of these important university publications to reach us. It opens with the minute adopted by the Board of Trustees on the death of their chairman, Mr. Henry W. Sage, who had made gifts to the University aggregating $1,175,000, and had given his services in many ways. The report reviews changes in the faculty, including some account of the work of Professors Dennis (analytical chemistry), Jacoby (civil engineering), Barr (mechanical engineering), and Trevor (chemistry), who were promoted to full professorships during the year. There were in the University 1,808 students, the number being practically the same as in 1893–4, before the requirements for admission were advanced. As Cornell is sometimes said to be developing into a great technological school rather than into a university it is interesting to note that in this period there has been a decrease of about 100 students in the departments of applied science and an increase of about 100 students in the academic departments. These numbered 593 students and there were 161 graduate students. President Schurman reviews the condition and work of the different departments and colleges of the University, the library, the grounds and the financial situation. The library now contains nearly 200,000 bound volumes; 10,000 have been added during the year. The financial statement is very brief. Except money paid from the Fayerweather estate, the University has received no bequests.

and but three small gifts. President Schurman's report, extending to 57 pages, is followed by appendices filling 117 pages, which give reports from other executive officers, the courses and attendance, and the publications by the University officers.

DISCUSSION AND CORRESPONDENCE.

ORGANIC SELECTION.

TO THE EDITOR OF SCIENCE: It seems to me that Professor Poulton's conclusion of the very interesting discussion on 'Organic Selection,' published in SCIENCE, October 15th, involves a serious confusion of ideas. He advocates the theory that natural selection confers on organisms the power of reacting adaptively to external forces. It is easy to conceive the effect of natural selection on an organism, assuming that the power of adaptation pre-exists; but it is incomprehensible that any amount of advantageous crossing should give the power of adaptation itself to an organism that does not already have it. Professor Poulton's arguments against that power being a property of a living organism are, I think, inconclusive. He dwells on the remarkable fact that physical forces awake responses which have to do with organic relations; but what of it? This shows only how powerful the tendency is. It is clear that any substance, animate or inanimate, reacts according to its own nature. If you drop a lighted match on to a pile of shavings, or on gunpowder, or into water, or on to a dog, certain pretty definite phenomena will occur in each case; yet the stimulus is the same; the recipient only is different. In the three earlier cases the results will be physical; in the case of the dog we reach the sphere of sensation. If the experiment be performed on a man we involve the moral sphere also, as he will either swear or refrain from swearing.

THOMAS DWIGHT.
ANATOMICAL DEPARTMENT,
HARVARD MEDICAL SCHOOL,
October 20, 1897.

A GASOLINE LAUNCH FOR FIELD WORK.

TO THE EDITOR OF SCIENCE: Last winter several papers and magazines, including SCIENCE (Vol. V., No. 119), noted the fact that I was constructing a gasoline launch for facilitating the study of paleontology and stratigraphic geology at Cornell University. Feeling that the results of this undertaking have been satisfactory in every way, and may be of interest to other investigators and teachers, I take pleasure in furnishing the following notes: First, as to what has been accomplished during the summer with this launch; second, why a naptha or gasoline launch is preferable to one propelled by steam.

July and August were spent on a long voyage from Ithaca to lower Chesapeake Bay and return, going *via* Erie Canal, Hudson River, Raritan River and Canal, Delaware River, Delaware and Chesapeake Canal, Chesapeake Bay and its many inflowing rivers. The special object of this expedition was to collect large quantities of Eocene and Miocene mollusca from Maryland and Virginia. Four students and myself constituted the party. During September a shorter excursion was made along the Erie Canal to Troy, N. Y., where Archæan, Cambrian, Ordovician, Silurian and Devonian outcrops were visited, either as they were found along the canal or at no great distance to the north or south. During term time the launch is being used for taking classes to fossiliferous outcrops along Cayuga Lake.

Now, a word as to why gasoline is preferable to steam:

1. Cost.—(*a*) Any well constructed boat 30 feet long, with a 6-horse power gasoline engine will run 800 miles on two barrels of oil; cost about $9.00 on an average, *i. e.*, a little over a cent a mile; (*b*) while on government waters no licensed engineer or pilot is required. With a few days' practice, under the direction of one acquainted with the engine, one learns his engine thoroughly and can as easily go up the Potomac to Washington as navigate his own mill-pond.

2. Freedom from government inspection.

3. There being no boiler or fire, the boat is light, roomy and cool.

4. When stopping at an outcrop no gasoline is being used. The whole machine is at a standstill, dead. But to start up and get under full speed requires less than a minute.

There are many other interesting points that ought to be touched on here, but space will

scarcely permit it. Those who may be interested in the subject are at liberty to make such inquiries of the writer as they see fit. Suffice it to say that in a country like our own, well traversed by water ways, a marine laboratory capable of rapid locomotion, at an exceedingly small cost, seems a very desirable adjunct to true university work in natural history subjects.

G. D. HARRIS.

CORNELL UNIVERSITY.

SCIENTIFIC LITERATURE.

Ueber Verwachsungsversuche mit Amphibienlarven. Von DR. G. BORN. Leipzig, W. Engelmann. 1897. (Reprinted from Archiv für Entwickelungsmechanik, Band IV.) 8vo. Pp. 224. Pls. I.–XI.

Professor Gustow Born is distinguished among living morphologists for the novelty and thoroughness of his investigations. It is to him that we owe the section modelling which is now so much used for the anatomical reconstruction of embryos, and which he has himself applied with brilliant results to the study of the development of the thyroid and of the heart. To him we owe also the experimental demonstration of the isotropism of the egg. In the present work we encounter again striking originality of method, coupled with extraordinary patience and thoroughness in the execution of the research. The method consists in the artificial union of two amphibian larvæ; this is accomplished by making a smooth cut on each larva, adpressing the two cut surfaces and allowing them to grow together; the natural fusion begins in half an hour to express itself and is complete in a few hours; in successful cases the united pair develop in unison and remain alive for weeks. Dr. Born's patience shows itself in the number and variety of fusions accomplished and in the exhaustive anatomical study of the developed monstrosities.

The only earlier experiments on fusion of two individuals were those of Trembley on Hydra, recently repeated by G. Wetzel. On the other hand, the announcement of Born's results has already occasioned a number of similar experiments on other animals. W. Roux appears to have first discovered the extraordinary power of the eggs and young larvæ of frogs of withstanding severe mechanical injury, and others have demonstrated the wonderful regenerative faculty of Amphibia during the early stages. Born has taken advantage of these characteristics to secure the concrescence of two individuals which develop afterwards as one. The spread of the ectoderms is the first step of the union, and there is in a short time a complete sheet of this tissue, with no visible break or trace of demarcation, extending from one larvæ to the other and covering the wound. This healing over is effected by the expansion of the sheet of ectoderms, and this expansion is not due to multiplication of the cells. Most of Born's experiments were made on larvæ of four millimeters (more or less) in length and on the following species: *Rana esculenta Bombinator igneus* and *Pelobates fuscus*; the larvæ of toads and of Rana fusca proved less favorable. Pieces of almost any size can be made to unite either of the same, or of different larvæ, and even of larvæ of two species. When the experiment succeeds such united pieces will live for about three weeks, or, in other words, until the supply of yolk material for the maintenance of growth is exhausted, but, if one or both the pieces have a digestive tract with mouth and arms, the united pieces may continue to develop indefinitely, and in such cases the blood channels of both species acquire open communication with one another, so that even when there is but one heart the blood circulates through both components. During the life of the fused larvæ, their development, their differentiation proceeds, each organ continues its progress. The development essentially follows the principles of Roux's mosaic theory.

The following schedule indicates the variety of successful unions accomplished by Professor Born:

A. Experiments on single larvæ.
  1. Pieces cut off and allowed to continue their development.
  2. Larva cut through and the pieces reunited.

B. Fusion of two larvæ, or parts of two larvæ.
  1. Both larvæ of the same species.
    a. Fusion of anterior with posterior pieces.
    b. Fusion by the ventral surfaces.
    c. Fusion of the posterior piece of one larva with the ventral side of another.

d. Fusion of the anterior piece of one larva with the ventral side of another.
e. Fusion of two posterior pieces.
f. Fusion of the heads of two larvæ.
g. Fusion of anterior pieces.

2. The larvæ belong to different species or even genera.
a. Fusion of the ventral surfaces.
b. Fusion of the posterior piece of one larva with the ventral surface of the other.
c. Fusion of an anterior with a posterior piece.
d. Fusion of the heads of two larvæ.

Every one of these unions was repeated many times, and the monograph presents an exact description of the anatomical condition of several specimens of each form of double larva, after the development had continued some weeks. These descriptions are based upon the examination of serial sections, the specimens being sacrificed on the microtomic altar. It is not using too strong a word to characterize the labor involved as enormous. The work, moreover, bears throughout the stamp of extreme conscientiousness.

It is impossible to enter here into details, but some of the general conclusions formulated by the author are so interesting that they are here presented. If, by the fusion, corresponding organs or their anlages are brought into contact they unite continuously by the concrescence of the specific tissue of the organ (the process might be appropriately named '*Histofusion*,' *Rev.*). If the anlages of unlike organs are brought in contact they become united by connective tissue. If the similar organs are hollow not only do their walls fuse, but also smooth open communication of their cavities is established, and in such cases it is not necessary that parts precisely corresponding should be joined. The different parts of the digestive tube will fuse, or the spinal cord will unite with the brain, and there will be produced a smooth passage from the cavity of one to that of the other, similarly in cases of fusion of the abdominal, pericardial or vascular cavities, of hearts, wolffian ducts, etc. Tissues are found united in this way which at the time of the union were still undifferentiated. Under certain conditions ectodermal and entodermal epithelia may become connected. The notochord takes an exceptional position in that the notochord of one piece does not concresce with that of another. The growing together of similar organs or tissues may occur in any plane or direction; there is no trace of polarity in the growth, such as Vöchting records for plants. The union of two pieces may be not only anatomical, but also physiological, and Born designates this as physiological symbiosis. It occurs in various degrees. In probably all cases the blood vessels are in open communication, so that the circulation is common to both components. A higher degree of symbiosis is marked in the cases where the intestine of the major larva has annexed a piece of the intestine of the minor, and both function together to the common advantage, or when the two larvæ have a stretch of intestine in common. The highest degree is reached when a whole end of the body, together with all its organs, is replaced, lengthened or doubled, for then the posterior piece from one larva works with the anterior piece of another, as if they were one individual. The highest degree is equally attained when the right and left halves of two larvæ are united in a single individual. The '*individuum*' is not dependent on the derivation from one egg. We have a single organism from two eggs (einen einheitlichen organismus aus zwei eiern). In the derivation from a single ovum there is no mystic, metaphysical unity.

The development, from the stage at which the experiments begin, depends upon self-differentiation of the single parts. No correlative influence of the surrounding parts can be recognized; the development is mosaic—Feis' organic areas (*organbildende Keimbezirke*) are partitioned off.

We commend this work to the attention of all biologists, and venture to predict that further important deductions will be garnered from these experiments of Professor Born, supplemented as they soon will be by additional researches. CHARLES S. MINOT.

The Concise Knowledge Library: Natural History. By R. LYDEKKER, W. F. KIRBY, B. B. WOODWARD, R. KIRKPATRICK, R. I. POCOCK,

R. BOWDLER SHARPE, W. GARSTANG, F. A. BATHER, H. M. BERNARD. New York, D. Appleton & Company. 1897. 8vo. Pp. 771. Price, $2.00.

The Concise Knowledge Library's *Natural History*—a misleading title inasmuch as the book contains no botany—treats of the animal kingdom from the higher mammalia down to the protozoa. Its authors, as may be seen from the above list, are Europeans, and the forms of life they describe and illustrate are, from the American standpoint, chiefly exotic. At the same time, where an abridged encyclopedia is wanted the book will be found convenient for reference.

The preface states that "the text is illustrated by upwards of five hundred original drawings made and reproduced expressly for the work." Those of the insects and some of the other invertebrates are fair; the remainder may probably be regarded as the worst batch of illustrations published in modern times. This is due partly to faulty drawing and partly to bad ink and poor printing. The type is small, and the volume as a whole has a cheap appearance, which ill fits the high reputation of its authors.

The mammals are treated first and come in for the largest share of attention (217 pages); then the birds, reptiles and fishes, and so on down the scale. Mammalogists will be amused to hear that the American black and grizzly bears "are now considered merely as varieties of the European species," and that "the stoat or ermine (*Mustela erminea*) and the weasel (*Mustela vulgaris*) are common to Europe, North and Central Asia, and North America." Perhaps the best feature of the book is its index, which occupies nearly fifty pages and is said to contain about ten thousand references.

C. H. M.

Citizen Bird: Scenes from Bird-Life in Plain English for Beginners. By MABEL OSGOOD WRIGHT and ELLIOTT COUES. With 111 illustrations by LOUIS AGASSIZ FUERTES. New York and London, The Macmillan Company. 8vo. Pp. 430. Price, $1.50.

Among the new books awaiting the reviewer on his recent return from the West is one which, from its authorship, attractive appearance and odd title, could not be put aside. 'Citizen Bird' is its name—a book for girls and boys. It is admirabiy written and is illustrated by a remarkable series of original drawings.

In order to test the book the reviewer called his children, two little girls, and read them the opening chapters. The younger (aged five years) was hardly able to follow the story, though interested in certain passages, but her elder sister (aged seven) was simply spellbound from first to last; from which it may be inferred that the book will hold the attention of children of seven and upwards.

The subject-matter is very cleverly woven into a story of a family of bird lovers in their country home at 'Orchard Farm.' The owner of the farm, who is a doctor and something of an ornithologist, takes the children out into the woods and fields and tells them about the birds, their habits and their value to man; and afterward, in his 'wonder room,' gives them special talks on particular species, which are grouped by some easily remembered characteristic, as 'a silver-tongued family' (bluebirds, robins and thrushes), 'Peepers and Creepers' (creepers, kinglets, chickadees and nuthatches) and so on. The children at once become enthusiastic observers and ask innumerable questions, which, in the main, are admirably answered. The story is charmingly told, kindling an interest in bird-life which is kept up to the end. The child is taught a multitude of entertaining facts about nature, and at the same time filled with a healthy sentiment against the wanton destruction of birds and their eggs.

A few of the statements are a little lax from the standpoint of scientific precision, and one or two of the incidents narrated are liable to tax one's credulity, as when one of the boys tells of brushing newly-fallen snow from the back of a live woodcock on its nest; but the book as a whole may be commended as by far the best bird book for boys and girls yet produced in America.

The illustrations deserve more than passing notice. They are uncommonly good half-tone reproductions of wash drawings by young Fuertes, whose phenomenal talent in grasping bird attitudes was first brought to the attention of the public in Miss Florence A. Merriam's

'*A' Birding on a Bronco*'. The present series of more than a hundred drawings, published for the first time in 'Citizen Bird,' fully sustains the artist's reputation. As would be expected in so large a series, a few are indifferent, but by far the greater number are remarkable for beauty, fidelity and power of expression. The pictures alone are worth the price of the book.

The typography and press work are of a high order of excellence, and the publishers are to be congratulated on the exceptional skill shown by their printer in handling difficult text figures. It is refreshing to find a book in the field of popular natural history which so distinctly raises the standard for its class and at the same time is offered for sale at so low a price.

C. H. M.

The Birds of Colorado. By W. W. COOKE. Fort Collins, Colorado, State Agricultural College, Agricultural Experiment Station. Bulletin No. 37. Technical Series No. 2. March, 1897. Pp. 1–143.

In view of the geographical situation of Colorado and its topographical features, a recent bulletin by Professor W. W. Cooke, of the State Agricultural College at Fort Collins, is of more than usual interest. It is a well annotated list of all the birds known to occur within the limits of the State. Other features—general discussion, historical résumé, classification of species as regards occurrence, and bibliography—contribute to its value. Considering the opportunity which the region offers, it is somewhat surprising that the author did not also attempt a definition and discussion of the life areas of the State.

The results have been derived largely from a summing up of previously published work, but in addition to this, much valuable new matter is included in the author's own notes and those which other observers placed at his disposal. The list is a large one, the number of species and subspecies attributed to the State being 363, of which 230 are breeders. To those previously recorded, 19 species are added. This makes an enviable total, but that it may still be increased is demonstrated by the outline of yet unworked territory. Colorado will always be an interesting ornithological field, and the present paper cannot fail to be of great service as a basis and stimulus for future work there.

W. H. OSGOOD.

SOCIETIES AND ACADEMIES.

BIOLOGICAL SOCIETY OF WASHINGTON, 280TH MEETING, SATURDAY, OCTOBER 23.

MR. F. A. LUCAS described 'A Dangerous Parasite of the Fur-seal,' stating that it was a nematode of the genus *Uncinaria* found in the sandy portions of the seal rookeries of the Pribilof islands, and caused the death of many young seals. Dr. C. W. Stiles discussed the structure, habits and life history of allied forms.

Dr. C. W. Stiles spoke of 'The International Committee on Zoological Nomenclature,' and of what had been accomplished at the meeting of 1897.

Mr. M. B. Waite presented a communicatign on 'A New Peach and Plum Disease,' caused by a species of mite attacking and killing the terminal bud of the very young trees. The resulting loss in the value of the trees was considerable, as many thousand trees would be affected in one nursery. A similar disease prevailed in the Japanese quince.

Mr. F. V. Coville spoke of 'The History and Distribution of *Abies shastensis*,' which he had found in a recent trip through the Cascade mountains of Oregon to extend along the range north of the Oregon-California line as far as latitude 43° 35′. It has long been confounded with *Abies nobilis*, which is, however, a tree of more northern distribution.

F. A. LUCAS,
Secretary.

UNIVERSITY OF WISCONSIN SCIENCE CLUB.

AT the meeting of the Club on October 15, 1897, Mr. H. A. Harding, in a paper on 'Bacterial Plant Diseases,' spoke of the first discovery by Professor Burrill, of Illinois, and of the tardiness with which European investigators recognized this work. He showed the extent to which bacterial diseases occur, especially among our garden vegetables. Then followed a discussion of a disease occurring in the cauliflower and cabbage. The bacteria find entrance at the water-pores of the leaf and also through

insect wounds, and the disease causes a blackening of the fibro-vascular bundles, followed by the death of the plant.

Mr. Comstock presented an account of research work in progress at the Washburn Observatory. The meridian circle has been employed for some years by Mr. Flint in determining the relative parallaxes of a list of stars selected with reference to large proper motion. The observations for the determination of nearly 100 parallaxes are completed and the reductions are well advanced, although but a small number of definitive results have yet been reached. In so far as these have been obtained they are very satisfactory in respect both of probable error and agreement with other determinations.

There was also described work done with the 40 cm. equatorial telescope in investigations of stellar color and upon the density of the supposed lunar atmosphere. A provisional result of the latter work is that this density cannot exceed one five-thousandth part of that of the earth's atmosphere at sea level.

WM. S. MARSHALL,
Secretary.

SCIENTIFIC JOURNALS.

The American Journal of Science, November.—'Geology of Southern Patagonia,' J. B. Hatcher: An account of observations made while collecting vertebrate fossils for Princeton University from May 1, 1896, to June 5, 1897, giving suggestions as to the age and origin of the different sedimentary deposits and the agencies which have determined the present topographical features. 'Some of the large Oysters of Patagonia,' A. E. Ortmann. 'Former Extension of the Appalachians across Mississippi, Louisiana and Texas,' J. C. Branner: Evidence for the theory announced in 1890 regarding the character and extent of the southwestern Appalachian depression. 'Combustion of Organic Substances in the Wet Way,' I. K. Phelps: Extension of the process applied in a previous article to carbon dioxide. 'Some Features of Pre-Glacial Drainage in Michigan,' E. H. Mudge.

The American Naturalist, October.—'Edward Drinker Cope, Naturalist—A Chapter in the History of Science' (Illustrated), Theodore Gill: Address by the retiring President of the American Association for the Advancement of Science. 'New Observations on the Origin of the Galapagos Islands, with Remarks on the Geological Age of the Pacific Ocean,' G. Baur: Part II., giving the geographical distribution of different animals in the Pacific and Indo-Pacific Ocean. The number contains a portrait of the late James Ellis Humphrey, one of the associate editors of the journal.

Journal of Geology, September-October.—'The Newark System of New Jersey,' H. Kümmel: Based on the Annual Report of the State Geologist for 1896. 'The Topography of California,' Noah Fields Drake: Based on a relief map of California constructed by the author on a scale of 1 inch to 12 miles, and a vertical scale of 1 inch to 12,000 feet. 'A Comparative Study of the lower Cretaceous Formations and Faunas of the United States,' Timothy W. Stanton: A thesis submitted for Ph.D. degree in Columbian University, containing a bibliography filling 14 pages. 'Correlation of the Devonian Faunas in Southern Illinois,' Stuart Weller: Argues that the Devonian faunas in southern Illinois are not related to the Iowan Devonian faunas, but are a western extension of the faunas of the New York province.

*ASPECTS OF AMERICAN ASTRONOMY.**

THE University of Chicago yesterday accepted one of the most munificent gifts ever made for the promotion of any single science, and with appropriate ceremonies dedicated it to the increase of our knowledge of the heavenly bodies. The President of your University has done me the honor of inviting me to supplement what was said on that occasion by some remarks of a more general nature.

One is naturally disposed to say first what is uppermost in his mind. At the present moment this will naturally be the general impression made by what has been seen and heard. The ceremonies were attended not only by a remarkable delegation of cititizens, but by a number of visiting astronomers, which seems large when we consider that the profession itself is not at all numerous in any country. As one of these, your guests, I am sure that I give expression only to their unanimous sentiment in saying that we have been extremely gratified in many ways by all that we have seen and heard. The mere fact of so munificent a gift to science cannot but excite universal admiration. We knew well enough that it was nothing more than might have been expected from the public spirit of this great West; but the first view

*Address by Professor Simon Newcomb, LL.D., on the occasion of the dedication of the Yerkes Observatory, University of Chicago, October 22, 1897.

of a towering snow peak is none the less impressive because you have learned in your geography how many feet high it is, and great acts are none the less admirable because they correspond to what you have heard and read, and might therefore be led to expect.

The next gratifying feature is the great public interest excited by the occasion. That the opening of a purely scientific institution should have led so large an assemblage of citizens to devote an entire day, including a long journey by rail, to the celebration of yesterday is something most suggestive from its unfamiliarity. A great many scientific establishments have been inaugurated during the last half century, but if on any such occasion so large a body of citizens has gone so great a distance to take part in the inauguration the fact has at the moment escaped from my mind.

That the interest thus shown is not confined to the hundreds of attendants, but must be shared by your great public, is shown by the unfailing barometer of journalism. Here we have a field in which the non-survival of the unfit is the rule in its most ruthless form ; the journals that we see and read are merely the fortunate few of a countless number, dead and forgotten, that did not know what the public wanted to read about. The eagerness shown by the representatives of your press in recording everything your guests would say was accomplished by an enterprise in making known everything that occurred, and, in case of an emergency requiring a heroic measure, what did not occur, which shows that smart journalists of the East must have learned their trade, or at least breathed their inspirations in these regions. I think it was some twenty years since I told a European friend that the eighth wonder of the world was a Chicago daily newspaper. Since that time the course of journalistic enterprise has been in the reverse direction, to that of the course of empire eastward, instead of westward.

It has been sometimes said—wrongfully I think—that scientific men form a mutual admiration society. One feature of the occasion made me feel that we, your guests, ought then and there to have organized such a society, and forthwith proceeded to business ; this feature consisted in the conferences on almost every branch of astronomy by which the celebration of yesterday was preceded. The fact that beyond the acceptance of a graceful compliment I contributed nothing to these conferences relieves me from the charge of bias or self-assertion in saying that they gave me a new and most inspiring view of the energy now being expended in research by the younger generation of astronomers. All the experience of the past leads us to believe that this energy will reap the reward which Nature always bestows upon those who seek her acquaintance from unselfish motives. In one way it might appear that little was to be learned from a meeting like that of the present week ; each astronomer may know by publications pertaining to the science what all the others are doing. But knowledge obtained in this way has a sort of abstractness about it, a little like our knowledge of the progress of civilization in Japan, or of the great extent of the Australian continent. It was, therefore, a most happy thought on the part of your authorities to bring together the largest possible number of visiting astronomers from Europe as well as America, in order that each might see, through the attrition of personal contact, what progress the others were making in their researches. To the visitors, at least, I am sure that the result of this meeting has been extremely gratifying. They earnestly hope, one and all, that the callers of the conference will not themselves be more disappointed in its

results; that, however little they may have actually to learn of methods and results, they will feel stimulated to well-directed efforts and find themselves inspired by thoughts which, however familiar, will now be more easily worked out.

We may pass from the aspects of the case as seen by the more strictly professional class to those more general aspects fitted to excite the attention of the great public. From the point of view of the latter it may well appear that the most striking feature of the celebration is to be found in the great amount of effort which it shows to be devoted to the cultivation of a field quite outside the ordinary range of human interests. A little more than two centuries ago Huyghens prefaced an account of his discoveries on the planet Saturn with the remark that many, even among the learned, might think he had been devoting to things too distant to interest mankind an amount of study which would better have been devoted to subjects of more immediate concern. It must be admitted that this fear has not deterred succeeding astronomers from pursuing their studies. The enthusiastic students whom we see around us are only a detachment from an army of investigators who, in many parts of the world, are seeking to explore the mysteries of creation. Why so great an expenditure of energy? Certainly not to gain wealth, for astronomy is perhaps the one field of scientific work which, in our expressive modern phrase, 'has no money in it.' It is true that the great practical use of astronomical science to the country and the world in affording us the means of determining positions on land and at sea is frequently pointed out. It is said that an Astronomer Royal of England once calculated that every meridan observation of the moon made at Greenwich was worth a pound sterling, on account of the help it would afford to the navigation of the ocean. An accurate map of the United States cannot be constructed without astronomical observations at numerous points scattered over the whole country, aided by data which great observatories have been accumulating for more than a century and must continue to accumulate in the future.

But neither the measurement of the earth, the making of maps, nor the aid of the navigator is the main object which the astronomers of to-day have in view. If they do not quite share the sentiment of that eminent mathematician who is said to have thanked God that his science was one which could not be prostituted to any useful purpose, they still know well that to keep utilitarian objects in view would only prove a handicap on their efforts. Consequently, they never ask in what way their science is going to benefit mankind.

As the great captain of industry is moved by the love of wealth and the politician by the love of power, so the astronomer is moved by the love of knowledge for its own sake, and not for the sake of its application. Yet he is proud to know that his science has been worth more to mankind than it has cost. He does not value its results merely as a means of crossing the ocean or mapping the country, for he feels that man does not live by bread alone. If it is not more than bread to know the place we occupy in the universe it is certainly something which we should place not far behind the means of subsistence. That we now look upon a comet as something very interesting, of which the sight affords us a pleasure unmixed with fear of war, pestilence or other calamity, and of which we therefore wish the return, is a gain that we cannot measure by money. In all ages astronomy has been an index to the civilization of the people who cultivated it. It has been crude or exact, enlightened or mingled with superstition, according to the current mode of thought. When once men understand

the relation of the planet on which they dwell to the universe at large superstition is doomed to speedy extinction. This alone is an object worth more than money.

Astronomy may fairly claim to be that science which transcends all others in its demands upon the practical application of our reasoning powers. Look at the stars that stud the heavens on a clear evening. What more hopeless problem to one confined to earth than that of determining their varying distances, their motions and their physical constitution? Everything on earth we can handle and investigate. But how investigate that which is ever beyond our reach, on which we can never make an experiment? On certain occasions we see the moon pass in front of the sun and hide it from our eyes. To an observer a few miles away the sun was not entirely hidden, for the shadow of the moon in a total eclipse is rarely 100 miles wide. On another continent no eclipse at all may have been visible. Who shall take a map of the world and mark upon it the line on which the moon's shadow will travel during some eclipse a hundred years hence? Who shall map out the orbits of the heavenly bodies as they are going to appear in a hundred thousand years? How shall we ever know of what chemical elements the sun and the stars are made? All this has been done, but not by the intellect of any one man. The road to the stars has been opened only by the efforts of many generations of mathematicians and observers, each of whom began where his predecessor had left off.

We have reached a certain stage where we know much about the heavenly bodies. We have mapped out our solar system with great precision. But how with that great universe of millions of stars in which our solar system is only a speck of star dust, a speck which a traveler through the wilds of space might pass a hundred times without notice? We have learned much about this universe, though our knowledge of it is still dim. We see it as a traveler on a mountain top sees a distant city in a cloud of mist, by a few specks of glimmering light from steeples or roofs. We want to know more about it, its origin and its destiny; its limits in time and space, if it has any; what function it serves in the universal economy. The journey is long, yet we want, in knowledge at least, to reach the stars. Hence we build observatories and train observers and investigators. Slow, indeed, is progress in the solution of the greatest of problems when measured by what we want to know. Some questions may require centuries, others thousands of years for their answer. And yet never was progress more rapid than during our time. In some directions our astronomers of to-day are out of sight of those of fifty years ago; we are even gaining heights which twenty years ago looked hopeless. Never before had the astronomer so much work, good, hard, yet hopeful work, before him as to-day. He who is leaving the stage feels that he has only begun and must leave his successors with more to do than his predecessors left him.

To us an interesting feature of this progress is the part taken in it by our own country. The science of our day, it is true, is of no country. Yet, we very appropriately speak of American science from the fact that our traditional reputation has not been that of a people deeply interested in the higher branches of intellectual work. Men yet living can remember when in the eyes of the universal church of learning all cisatlantic countries, our own included, were *partes infidelium.*

Yet American astronomy is not entirely of our generation. In the middle of the last century Professor Winthrop of Harvard was an industrious observer of eclipses and kindred phenomena, whose work was recorded in the transactions of learned socie-

ties. But the greatest astronomical activity during our colonial period was that called out by the transit of Venus in 1769, which was visible in this country. A committee of the American Philosophical Society at Philadelphia organized an excellent system of observations, which we now know to have been fully as successful, perhaps more so, than the majority of those made on other continents, owing mainly to the advantages of air and climate. Among the observers was the celebrated Rittenhouse, to whom is due the distinction of having been the first American astronomer whose work has an important place in the history of the science. In addition to the observations which he has left us, he was the first inventor or proposer of the collimating telescope, an instrument which has become almost a necessity wherever accurate observations are made. The fact that the subsequent invention by Bessel was quite independent does not detract from the merits of either.

Shortly after the transit of Venus which I have mentioned, the War of the Revolution commenced. The generation which carried on that war, and the following one which formed our Constitution and laid the bases of our political institutions, were naturally too much occupied with these great problems to pay much attention to pure science. When the great mathematical astronomers of Europe were laying the foundation of celestial mechanics their meetings were a sealed book to every one on this side the Atlantic, and so remained till Bowditch appeared, early in the present century. His translation of the *Mécanique Céleste* made an epoch in American science by bringing the great work of Laplace down to the reach of the best American students of his time.

American astronomers must always honor the names of Rittenhouse and Bowditch. And yet, in one respect their work was disappointing of results. Neither of them was the founder of a school. Rittenhouse left no successor to carry on his work. The help which Bowditch afforded his generation was invaluable to isolated students who, here and there, dived alone and unaided into the mysteries of the celestial motions. His work was not mainly in the field of observational astronomy, and therefore did not materially influence that branch of the science. In 1832 Professor Airy, afterward Astronomer Royal of England, made a report to the British Association on the condition of practical astronomy in various countries. In this report he remarked that he was unable to say anything about American astronomy because, so far as he knew, no public observatory existed in the United States.

William C. Bond, afterward famous as the first Director of the Harvard Observatory, was at that time making observations with a small telescope, first near Boston, and afterward at Cambridge. But with so meager an outfit his establishment could scarcely lay claim to being an astronomical observatory, and it was not surprising if Airy did not know anything of his modest efforts.

If at this time Professor Airy had extended his investigations into yet another field, with a view of determining the prospects for a great city at the cite of Fort Dearborn, on the southern shore of Lake Michigan, he would have seen as little prospect of civic growth in that region as of a great development of astronomy in the United States at large. A plat of the proposed town of Chicago had been prepared two years before, when the place contained perhaps half a dozen families. In the same month in which Professor Airy made his report, August, 1832, the people of that place, then numbering twenty-eight voters, decided to become incorporated, and selected five trustees to carry on their government.

In 1837 a city charter was obtained from

the Legislature of Illinois. The growth of this infant city, then small even for an infant, into the great commercial metropolis of the West has been the just pride of its people and the wonder of the world. I mention it now because of a remarkable coincidence. With this civic growth has quietly gone on another, little noted by the great world, and yet in its way equally wonderful and equally gratifying to the pride of those who measure greatness by intellectual progress. If it be true that "in nature nothing is great but man, in man nothing is great but mind," then may knowledge of the universe be regarded as the true measure of progress. I, therefore, invite attention to the fact that American astronomy began with your city, and has slowly but surely kept pace with it until to-day our country stands second only to Germany in the number of researches being prosecuted, and second to none in the number of men who have gained the highest recognition by their labors.

In 1836 Professor Albert Hopkins, of Williams College, and Professor Elias Loomis, of Western Reserve College, Ohio, both commenced little observatories. Professor Loomis went to Europe for all his instruments, but Hopkins was able even then to get some of his in this country. Shortly afterward a little wooden structure was erected by Captain Gilliss on Capitol Hill, at Washington, and supplied with a transit instrument for observing moon culminations in conjunction with Captain Wilkes, who was then setting out on his exploring expedition to the southern hemisphere. The date of these observatories was practically the same as that on which a charter for the City of Chicago was obtained from the Legislature. With their establishment the population of your city had increased to 703.

The next decade, 1840 to 1850, was that in which our practical astronomy seriously commenced. The little observatory of Captain Gilliss was replaced by the Naval Observatory, erected at Washington during the years 1843–4 and fitted out with what were then the most approved instruments. About the same time the appearance of the great comet of 1843 led the citizens of Boston to erect the observatory of Harvard College. Thus it is little more than half a century since the two principal observatories in the United States were established. But we must not for a moment suppose that the mere erection of an observatory can mark an epoch in scientific history. What must have made the decade of which I speak ever memorable in American astronomy was not merely the erection of buildings, but the character of the work done by astronomers away from them as well as in them.

The Naval Observatory very soon became famous by two remarkable steps which raised our country to an important position among those applying modern science to practical uses. One of these consisted of the researches of Sears Cook Walker on the motion of the newly-discovered planet Neptune. He was the first astronomer to determine fairly good elements of the orbit of that planet, and, what is yet more remarkable, he was able to trace back the movement of the planet in the heavens for half a century and to show that it had been observed as a fixed star by Lalande in 1795 without the observer having any suspicion of the true character of the object.

The other work to which I refer was the application to astronomy and to the determination of longitudes of the chronographic method of registering transits of stars or other phenomena requiring an exact record of the instant of their occurrence. It is to be regretted that the history of this application has not been fully written. In some points there seems to be as much obscurity as with the discovery of ether as an an-

æsthetic, which took place about the same time. Happily, no such contest has been fought over the astronomical as over the surgical discovery, the fact being that all who are engaged in the application of the new method were more anxious to perfect it than they were to get credit for themselves. We know that Saxton, of the Coast Survey; Michell and Locke, of Cincinnati; Bend at Cambridge, as well as Walker and other astronomers at the Naval Observatory, all worked at the apparatus; that Maury seconded their efforts with untiring zeal, that it was used to determine the longitude of Baltimore as early as 1844 by Captain Wilkes, and that it was put into practical use in recording observations at the Naval Observatory as early as 1846.

At the Cambridge Observatory the two Bonds, father and son, speedily began to show the stuff of which the astronomer is made. A well devised system of observations was put in operation. The discovery of the dark ring of Saturn and of a new satellite to that planet gave additional fame to the establishment.

Nor was activity confined to the observational side of the science. The same decade of which I speak was marked by the beginning of Professor Pierce's mathematical work, especially his determination of the perturbations of Uranus and Neptune. At this time commenced the work of Dr. B. A. Gould, who soon became the leading figure in American astronomy. Immediately on graduating at Harvard, in 1845, he determined to devote all the energies of his life to the prosecution of his favorite science. He studied in Europe for three years, took the doctor's degree at Göttingen, came home, founded the *Astronomical Journal*, and took an active part in that branch of the work of the Coast Survey which included the determination of longitudes by astronomical methods.

An episode which may not belong to the history of astronomy must be acknowledged to have had a powerful influence in exciting public interest in that science. Professor O. M. Mitchel, the founder and first Director of the Cincinnati Observatory, made the masses of our intelligent people acquainted with the leading facts of astronomy by courses of lectures which, in lucidity and eloquence, have never been excelled. The immediate object of the lectures was to raise funds for establishing his observatory and fitting it out with a fine telescope. The popular interest thus excited in the science had an important effect in leading the public to support astronomical research. If public support, based on public interest, is what has made the present fabric of American astronomy possible, then should we honor the name of a man whose enthusiasm leavened the masses of his countrymen with interest in our science.

The Civil War naturally exerted a depressing influence upon our scientific activity. The cultivator of knowledge is no less patriotic than his fellow citizens, and vies with them in devotion to the public welfare. The active interest which such cultivators took, first in the prosecution of the war and then in the restoration of the Union, naturally distracted their attention from their favorite pursuits. But no sooner was political stability reached than a wave of intellectual activity set in, which has gone on increasing up to the present time. If it be true that never before in our history has so much attention been given to education as now; that never before did so many men devote themselves to the diffusion of knowledge, it is no less true that never was astronomical work so energetically pursued among us as now. One deplorable result of the Civil War was that Gould's *Astronomical Journal* had to be suspended. Shortly after the restoration of peace, instead of re-establishing the journal, its founder conceived the project of exploring

the southern heavens. The northern hemisphere being the seat of civilization, that portion of the sky which could not be seen from our latitudes was comparatively neglected. What had been done in the southern hemisphere was mostly the occasional work of individuals and of one or two permanent observatories. The latter were so few in number and so meager in their outfit that a splendid field was open to the inquirer. Gould found the patron which he desired in the government of the Argentine Republic, on whose territory he erected what must rank in the future as one of the memorable astronomical establishments of the world. His work affords a most striking example of the principle that the astronomer is more important than his instruments. Not only were the means at the command of the Argentine observatory slender in the extreme when compared with those of the favored institutions of the north, but, from the very nature of the case, the Argentine Republic could not supply trained astronomers. The difficulties thus growing out of the administration cannot be overestimated. And yet the sixteen great volumes in which the work of the institution has been published will rank in the future among the classics of astronomy.

Another wonderful focus of activity, in which one hardly knows whether he ought most to admire the exhaustless energy or the admirable ingenuity which he finds displayed, is the Harvard Observatory. Its work has been aided by gifts which have no parallel in the liberality that prompted them. Yet without energy and skill such gifts would have been useless. The activity of the establishment includes both hemispheres. Time would fail to tell how it has not only mapped out important regions of the heavens from the north to the south pole, but analyzed the rays of light which come from hundreds of thousands of stars by recording their spectra in permanence on photographic plates. The work of the establishment is so organized that a new star cannot appear in any part of the heavens, nor a known star undergo any noteworthy change, without immediate detection by the photographic eye of one or more little telescopes, all seeing and never sleeping policemen, that scan the heavens unceasingly while the astronomer may sleep, and report in the morning every case of irregularity in the proceedings of the heavenly bodies.

Yet another example showing what great results may be obtained with limited means is afforded by the Lick Observatory, of California. During the ten years of its activity its astronomers have made it known the world over by its unequaled works and discoveries, too varied and numerous to be even mentioned at the moment.

The astronomical work of which I have thus far spoken has been almost entirely that done at observatories. I fear that I may in this way have strengthened an erroneous impression that the seat of important astronomical work is necessarily connected with an observatory. It must be admitted that an institution which has a local habitation and a magnificent building commands public attention so strongly that valuable work done elsewhere may be overlooked. A very important part of astronomical work is done away from telescopes and meridian circles, and requires nothing but a good library for its prosecution. One who is devoted to this side of the subject may often feel that the public does not appreciate his work at its true relative value, from the very fact that he has no great buildings or fine instruments to show. I may, therefore, be allowed to claim as an important factor in the American astronomy of the last half century an institution of which few have heard and which has been overlooked because there was nothing about it to excite attention.

In 1849 the *American Nautical Almanac* office was established by a Congressional appropriation. The title of this publication is somewhat misleading in suggesting a simple enlargement of the family almanac which the sailor is to hang up in his cabin for daily use. The fact is that what started more than a century ago as a nautical almanac has since grown into an astronomical ephemeris for the publication of everything pertaining to times, seasons, eclipses and the motions of the heavenly bodies. It is the work in which astronomical observations made in all the great observatories of the world are ultimately utilized for scientific and public purposes. Each of the leading nations of western Europe issues such a publication. When the preparation and publication of the *American Ephemeris* was decided upon the office was first established in Cambridge, the seat of Harvard University, because there could most readily be secured the technical knowledge of mathematics and theoretical astronomy necessary for the work.

A field of activity was thus opened, of which a number of able young men who have since earned distinction in various walks of life availed themselves. The head of the office, Commander Davis, adopted a policy well fitted to promote their development. He translated the classic work of Gauss, *Theovia Motus Corporum Cœlestium*, and made the office a sort of informal school, not, indeed, of the modern type, but rather more like the classic grove of Hellas, where philosophers conducted their discussions and profited by mutual attrition. When, after a few years of experience, methods were well established and a routine adopted, the office was removed to Washington, where it has since remained. The work of preparing the ephemeris has, with experience, been reduced to a matter of routine which may be continued indefinitely with occasional changes in methods and data and improvements to meet the increasing wants of investigators.

The mere preparation of the ephemeris includes but a small part of the work of mathematical calculation and investigation required in astronomy. One of the great wants of the science to-day is the re-reduction of the observations made during the first half of the present century, and even during the last half of the preceding one. The labor which could profitably be devoted to this work would be more than that required in any one astronomical observatory. It is unfortunate for this work that a great building is not required for its prosecution, because its needfulness is thus very generally overlooked by that portion of the public interested in the progress of science. An organization especially devoted to it is one of the scientific needs of our time.

In such an epoch-making age as the present it is dangerous to cite any one step as making a new epoch. Yet it may be that when the historian of the future reviews the science of our day he will find the most remarkable feature of the astronomy of the last twenty years of our century to be the discovery that this steadfast earth of which the poets have told us is not after all quite steadfast; that the north and south poles move about a very little, describing curves so complicated that they have not yet been fully marked out. The periodic variations of latitude thus brought about were first suspected about 1880, and announced with some modest assurance by Küstner, of Berlin, a few years later. The progress of astronomical opinion from incredulity to confidence, was extremely slow until, about 1890, Chandler, of the United States, by an exhaustive discussion of innumerable results of observations, showed that the latitude of every point on the earth was subject to a double oscillation, one having the period of a year, the other of 427 days

Notwithstanding the remarkable parallel between the growth of American astronomy and that of your city, one cannot but fear that if a foreign observer had been asked only half a dozen years ago at what point in the United States a great school of theoretical and practical astronomy, aided by an establishment for the exploration of the heavens, was likely to be established by the munificence of private citizens, he would have been wiser than most foreigners had he guessed Chicago. Had this place been suggested to him I fear he would have replied that were it possible to utilize celestial knowledge in acquiring earthly wealth here would be the most promising seat for such a school. But he would need to have been a little wiser than his generation to reflect that wealth is at the base of all progress in knowledge and the liberal arts; that it is only when men are relieved from the necessity of devoting all their energies to the immediate wants of life that they can lead intellectual lives, and that we should therefore look to the most enterprising commercial center as the likeliest seat for a great scientific institution.

Now we have the school, and we have the observatory, which we hope will in the near future do work that will cast luster on the name of its founder as well as on the astronomers who may be associated with it. You will, I am sure, pardon me if I make some suggestions on the subject of the future needs of the establishment. We want this newly founded institution to be a great success, to do work which shall show that the intellectual productiveness of your community will not be allowed to lag behind its material growth. The public is very apt to feel that when some munificent patron of science has mounted a great telescope under a suitable dome and supplied all the apparatus which the astronomer wants to use success is assured. But such is not the case. The most important requisite, one more difficult to command than telescopes or observatories, may still be wanting. A great telescope is of no use without a man at the end of it, and what the telescope may do depends more upon this appendage than upon the instrument itself. The place which telescopes and observatories have taken in astronomical history are by no means proportional to their dimensions. Many a great instrument has been a mere toy in the hands of its owner. Many a small one has become famous. Twenty years ago there was here in your own city a modest little instrument which, judged by its size, could not hold up its head with the great ones even of that day. It was the private property of a young man holding no scientific position and scarcely known to the public. And yet that little telescope is to-day among the famous ones of the world, having made memorable advances in the astronomy of double stars and shown its owner to be a worthy successor of the Herschels and the Struves in that line of work.

A hundred observers might have used the appliances of the Lick Observatory for a whole generation without finding the fifth satellite of Jupiter; without successfully photographing the cloud forms of the Milky Way; without discovering the extraordinary patches of nebulous light, nearly or quite invisible to the human eye, which fill some regions of the heavens.

When I was in Zurich last year I paid a visit to the little but not unknown observatory of its famous polytechnic school. The professor of astronomy was especially interested in the observations of the sun with the aid of the spectroscope, and among the ingenious devices which he described, not the least interesting was the method of photographing the sun by special rays of the spectrum which had been worked out at the Kenwood Observatory in Chicago. The Kenwood Observatory is not, I believe, in the eye of the public one of the

noteworthy institutions of your city which every visitor is taken to see, and yet this invention has given it an important place in the science of our day.

Should you ask me what are the most hopeful features in the great establishment which you are now dedicating, I would say that they are not alone to be found in the size of your unequaled telescope, nor in the cost of the outfit, but in the fact that your authorities have shown their appreciation of the requirements of success by adding to the material outfit of the establishment the three men whose works I have described.

Gentlemen of the Trustees, allow me to commend to your fostering care the men at the end of the telescope. The constitution of the astronomer shows curious and interesting features. If he is destined to advance the science by works of real genius he must, like the poet, be born, not made. The born astronomer, when placed in command of a telescope, goes about using it as naturally and effectively as the babe avails itself of its mother's breast. He sees intuitively what less-gifted men have to learn by long study and tedious experiment. He is moved to celestial knowledge by a passion which dominates his nature. He can no more avoid doing astronomical work, whether in the line of observations or research, than the poet can chain his Pegasus to earth. I do not mean by this that education and training will be of no use to him. They will certainly accelerate his early progress. If he is to become great on the mathematical side, not only must his genius have a bent in that direction, but he must have the means of pursuing his studies. And yet I have seen so many failures of men who had the best instruction, and so many successes of men who scarcely learned anything of their teachers, that I sometimes ask whether the great American celestial mechanician of the twentieth century will be a graduate of a university or of the backwoods.

Is the man thus moved to the exploration of nature by an unconquerable passion more to be envied or pitied? In no other pursuit does success come with such certainty to him who deserves it. No life is so enjoyable as that whose energies are devoted to following out the inborn impulses of one's nature. The investigator of truth is little subject to the disappointments which await the ambitious man in other fields of activity. It is pleasant to be one of a brotherhood extending over the world in which no rivalry exists except that which comes out of trying to do better work than anyone else, while mutual admiration stifles jealousy. And yet, with all these advantages, the experience of the astronomer may have its dark side. As he sees his field widening faster than he can advance he is impressed with the littleness of all that can be done in one short life. He feels the same want of successors to pursue his work that the founder of a dynasty may feel for heirs to occupy his throne. He has no desire to figure in history as a Napoleon of science whose conquests must terminate with his life. Even during his active career his work may be of such a kind as to require the cooperation of others and the active support of the public. If he is disappointed in commanding these requirements, if he finds neither cooperation nor support, if some great scheme to which he may have devoted much of his life thus proves to be only a castle in the air, he may feel that nature has dealt hardly with him in not endowing him with passions like to those of other men.

In treating a theme of perennial interest one naturally tries to fancy what the future may have in store. If the traveler contemplating the ruins of some ancient city which in the long ago teemed with the life and activities of generations of men sees

every stone instinct with emotion and the dust alive with memories of the past, may he not be similarly impressed when he feels that he is looking around upon a seat of future empire, a region where generations yet unborn may take a leading part in moulding the history of the world? What may we not expect of that energy which in sixty years has transformed a straggling village into one of the world's great centers of commerce? May it not exercise a powerful influence on the destiny not only of the country, but of the world? If so, shall the power thus to be exercised prove an agent of beneficence, diffusing light and life among nations, or shall it be the opposite? The time must come ere long when wealth shall outgrow the field in which it can be profitably employed. In what direction shall its possessors then look? Shall they train a posterity which will so use its power as to make the world better that it has lived in it? Will the future heir to great wealth prefer the intellectual life to the life of pleasure?

We can have no more hopeful answer to these questions than the establishment of this great university in the very focus of the commercial activity of the West. Its connection with the institution we have been dedicating suggests some thoughts on science as a factor in that scheme of education best adapted to make the power of a wealthy community a benefit to the race at large. When we see what a factor science has been in our present civilization, how it has transformed the world and increased the means of human enjoyment by enabling men to apply the powers of nature to their own uses, it is not wonderful that it should claim the place in education hitherto held by classical studies. In the contest which has thus arisen I take no part but that of a peacemaker, holding that it is as important to us to keep in touch with the traditions of our race and to cherish the thoughts which have come down to us through the centuries as it is to enjoy and utilize what the present has to offer us. Speaking from this point of view, I would point out the error of making the utilitarian applications of knowledge the main object in its pursuit. It is a historic fact that abstract science, science pursued without any utilitarian end, has been at the basis of our progress in the application of knowledge. If in the last century such men as Galvani and Volta had been moved by any other motive than love of penetrating the secrets of nature they would never have pursued the seemingly useless experiments they did, and the foundations of electrical science would not have been laid. Our present applications of electricity did not become possible until Ohm's mathematical laws of the electric current, which when first made known seemed little more than mathematical curiosities, had become the common property of inventors. Professional pride on the part of our own Henry led him, after making the discoveries which rendered the telegraph possible, to go no further in their application of his discoveries, and to live and die without receiving a dollar of the millions which the country has won through his agency.

In the spirit of scientific progress thus shown we have patriotism in its highest form—a sentiment which does not seek to benefit the country at the expense of the world, but to benefit the world by means of one's country. Science has its competition, as keen as that which is the life of commerce. But its rivalries are over the question who shall contribute the most and the best to the sum-total of knowledge—who shall give the most, not who shall take the most. Its animating spirit is love of truth. Its pride is to do the greatest good to the greatest number. It embraces not only the whole human race, but all nature in its scope. The public spirit of which this city is the focus has made the desert blossom as

the rose, and benefited humanity by the diffusion of the material products of the earth. Should you ask me how it is in the future to use its influence for the benefit of humanity at large, I would say, look at the work now going on in these precincts, and study its spirit. Here are the agencies which will make 'the voice of law the harmony of the world.' Here is the love of country blended with the love of the race. Here the love of knowledge is as unconfined as your commercial enterprise. Let not your youth come hither merely to learn the forms of vertebrates and the properties of oxides, but rather to imbibe that Catholic spirit which, animating their ever-growing energies, shall make their power an agent of beneficence to all mankind.

S. NEWCOMB.

WASHINGTON, D. C.

THE YERKES OBSERVATORY.

THE opening of the Yerkes Observatory has been an important event in the progress of science. The last masterpiece of Alvan G. Clark, the forty-inch refractor, has been appropriately established. A great institution for all branches of research in the related fields of astronomy and astrophysics has begun its activity. The University of Chicago has made an important addition to its already large equipment for the discovery and teaching of scientific truth.

A series of conferences, attended by a representative gathering of some sixty of the astronomers and astrophysicists of the country, occupied the three days preceding the formal exercises of dedication on October 21st and 22d. The program, as printed in the recent number of this JOURNAL (No. 147, October 22d) was carried out with but minor changes.

Stimulating discussions followed the presentation of many of the papers, in which a delightful feature was the participation of Professor Carl Runge, of Hannover. Unfortunately, a necessary postponement of the date of the exercises had made it impossible for Professor Schuster, of Manchester, Eng., and M. Deslandres, of Paris, to remain for the conferences.

The demonstrations, in the various laboratories of the Observatory, of new and interesting phenomena formed an important part of the program. The weather was not sufficiently favorable to permit the exhibition, with the great telescope, of many of the celestial objects as planned, but all present on the first two days had the opportunity of testing the light-grasp of the instrument on double stars and nebulæ, and in connection with the solar spectroscope.

The generous hospitality of the University provided for its scientific guests during the week unique entertainment in the spacious rooms of the Observatory itself, and the arrangements for this rather serious undertaking were admirably carried out, with the effective cooperation of a well-known Chicago caterer. To the full extent of their capacity the homes of the resident astronomers were also thrown open to their friends.

The location of the Observatory, selected after long deliberation and full examination of the available situations, commends itself at once, aside from its natural beauty, by reason of its isolation from traffic and manufacturing, a favorable condition which is likely to continue into an indefinite future. The center of motion of the great refractor is about 80 meters above the level of Lake Geneva, which is about 600 meters distant, the elevation above sea-level being about 400 meters. The railway station and post office are over a kilometer distant, at Williams Bay, Wisconsin, on the Chicago and Northwestern Railway, at a distance of 120 kilometers, or two and one-half hours, from Chicago.

The Observatory building, of brown Ro-

man brick, with terra cotta trimmings, is in the form of a Latin cross, having a longer axis of one hundred meters, with the great tower and dome at its western end, and with two smaller (ten-meter) domes at the northern and southern extremities of the shorter axis. A meridian room, with double sheet-iron walls, is at the eastern end of the building. The space of thirty-two meters in the attic between the small towers serves as a heliostat room. The main floor of the building contains offices, computing rooms, spectroscopic laboratories, an instrument and a photographic room, a chemical laboratory, a lecture room, library and reception room. The lower story, or basement, contains a concave grating room, an emulsion, an enlarging and a photographic dark room, and a constant temperature room. Very important features of this floor are the optical and the instrument shops, well supplied with machines and tools. Here large instruments are being constructed, and a sixty-inch glass reflector is now being ground by the optician.

The great dome, twenty-seven meters in diameter and eighteen meters in height, is provided with a rising floor having a vertical range of seven meters and operated by electric motors. This floor is a very essential feature in working with a telescope of sixty-two feet focal length and successfully overcomes what would otherwise be almost insurmountable (acrobatic) difficulties in observing. The massive iron and steel mounting of the forty-inch telescope (constructed, as were the dome and rising floor, by Warner and Swazey), is operated by electric motors regulated at the eye-end. The driving clock controls the motion of a mass of twenty tons.

The tests of the optical efficiency of the telescope have been thoroughly satisfactory. It has also been already demonstrated that the 'seeing' by day is excellent at Williams Bay, a fortunate condition in view of the disturbed day atmosphere at the Lick Observatory, but it is not to be expected that the night seeing can equal that at Mt. Hamilton.

The northeastern dome, nine meters in diameter, shelters the telescope formerly at the Kenwood Observatory, having two 12-inch objectives, visual and photographic. The southeast tower will for the present be occupied by a reflecting telescope. The equipment of the Yerkes Observatory in solar and stellar spectroscopes, gratings and kindred apparatus is already large. The gifts of Mr. Yerkes have included: For the objective, $66,000; for the equatorial mounting, $55,000; for the dome and rising floor, $45,000; for the building and smaller domes, stellar spectrograph, steam heating plant and power house, engine, dynamo and motors, over $145,000. The fifty-five acres of land, valued at $50,000, was given by Mr. John Johnston, Jr.; the instruments of the Kenwood Observatory by Mr. W. E. Hale; and $7,000 for a 10-inch photographic telescope, with building and dome, by Miss Catherine Bruce, of New York, to whose liberality astronomy owes much.

The address at the formal exercises of dedication was delivered in the ninety-foot dome, before a company of six hundred of the officers and guests of the University, by Professor J. E. Keeler on 'The Importance of Astrophysical research and the relation of Astrophysics to other physical sciences.' In a few well chosen words Mr. Charles T. Yerkes presented the deed of the institution to the President of the Trustees of the University, who responded in their behalf, as did President Harper for the Faculty. After a luncheon and inspection of the Observatory a special train conveyed the visitors to Chicago.

On the following day, October 22d, striking demonstrations were given, at the Ryerson Physical Laboratory by Professors Michel-

son and Stratton, of the applications of the interference refractometer and of the effect of a magnet upon radiation recently discovered by Zeeman. Professor Michelson also exhibited a harmonic analyzer, which may, perhaps, find application to certain pending problems of astronomy. The visiting scientists were entertained at luncheon by the President of the University and Mrs. Harper, and at 3 p. m. an address on 'Aspects of American Astronomy' was delivered by Professor Simon Newcomb. Finally the liberal hospitality of Mr. Yerkes provided a banquet in the evening for the visiting scientists.

The work of the Yerkes Observatory has thus been formally inaugurated. The aims of the institution as expressed by the President cannot fail to meet the approval of all friends of science:

"It is proper that a word should be said on behalf of the Faculty with respect to the policy which shall control the University in the use it shall make of the Observatory. The founder has indicated his desire in definite form that the Observatory shall not be used for popular purposes. Situated as it is, in close proximity to a village of large size, and within a short distance of so great a city as Chicago, it would be comparatively easy for the astronomers to occupy their entire time in exhibiting the instruments to the public. For the present it is the desire of the donor and the decision of the Trustees that the Observatory shall not be open to the public.

"In every department of science there is opportunity to-day for the development of what might be called the sensational. In no subject is this possibility greater than in that of astronomy. The work of not a few observatories and of not a few astronomers has been seriously injured by the desire to do and say that which will attract public attention. The Yerkes Observatory will strenuously oppose every tendency of this character, and will make every effort to represent only that kind of work which is of solid and substantial character.

"So much for the negative side. As to the positive policy of the Observatory, I quote from a statement of the Director: 'The policy of the Yerkes Observatory will be: (1) To derive the greatest possible return from the use of the large telescope it is evident that special attention should be given to (*a*) micrometrical observations of stars, satellites, comets, nebulæ, etc.; (*b*) solar investigations, both visual and photographic; and (*c*) spectroscopic researches on the chemical composition of the stars and their motion toward or from the earth. The present staff is sufficient to permit much of this work to be taken up to advantage. Another astronomer will be needed to develop the spectroscopic work, which is, probably, the most important work the Observatory can undertake, on account of its great light-gathering power.

"'(2) To provide for the investigation of any phase of an astronomical or related physical problem. Most American observatories are unprovided with the instruments and laboratories necessary for the interpretation of the phenomena constantly encountered in spectroscopic observations of the heavenly bodies. Spectroscopic laboratories, on the other hand, are not equipped to carry their investigations beyond the artificial boundaries of physics into the realm of astronomy. It is hoped that the Yerkes Observatory may ultimately be in a position to represent both the astronomical and the physical sides of astrophysical work, and at the same time provide the best facilities for research work in astronomy of position.'"

The present staff of the Observatory consists of Professor George E. Hale, Director; Professors S. W. Burnham, E. E. Barnard, F. L. O. Wadsworth; Mr. F. Ellerman, Assistant; Mr. G. W. Ritchey, Optician.

It would appear an urgent need that adequate endowment should be supplied for the maintenance of this splendid institution at the high degree of efficiency of which it is so capable.

EDWIN B. FROST.

THE ALUMNI BIOLOGICAL EXPEDITION OF NEW YORK UNIVERSITY TO THE BERMUDAS.

THE archipelago of the Bermudas was chosen as the ground for the first expedition of the Biological Department of the University for several reasons, among them the following: the means of communication, by the steamships of the Quebec S. S. Co., was easy; they seemed to afford a tropical marine fauna in abundance for study; they were free from the malarious diseases of the West Indies, the fatality of which was so sadly proved this summer in the expedition to Jamaica, and it seemed worth while to investigate the conditions under which a station might be established for permanent research.

Thanks to a number of alumni who made liberal contributions to the enterprise, the party left New York for Hamilton on June 3d. The party consisted of Dr. C. L. Bristol, in charge; Mr. Warren H. Everett, instructor, and Messrs. Brush, Carpenter, Brown, Rosenthal and Grose, of the University; Dr. Walter M. Rankin, of Princeton University, and Dr. Tarleton H. Bean, late of the U. S. Fish Commission and now Director of the Aquarium in New York City. The party was joined later by Mr. Ernest Haycock, of Harvard University. The last of the party arrived in New York on August 8th. Headquarters were established at the Harrington House, about six miles from Hamilton and situated on the narrow strip of land separating Harrington Sound from Castle Harbor. A vacant house near the shore of Castle Harbor was transformed into a comfortable laboratory, and from this as a center trips were made in various directions.

The most attention was given to a search for the various forms and a careful survey of the general conditions subtending their abundance and collection, so that, taken as a whole, the work might prove a reconnaissance and furnish knowledge for future investigations. In this the expedition was fairly successful and would have been much more so but for a long spell of southwest wind which prevented off-shore work, excepting for a few days. One instance of this may be given. Captain Meyers, of St. Georges, very kindly put his large ocean-going tug and a diver at our disposal to go to North Rock, and for a whole week we waited before a favorable morning came, but on that day, just as we arrived at the collecting ground, a heavy wind prevented any serious work. Our work was confined mainly to the lee shores and here we were greatly rewarded. Of corals the genera *Diploria*, *Meandrina*, *Astrea*, *Siderastrea*, *Porites*, *Isophyllia*, *Oculina* and *Mycedium* were found; of gorgonians, *Rhipidogorgia* and *Gorgonia*. The Actinaria are very abundant and our collections are numerous. We found but few hydroids and a millespore coral. The Medusæ and Hydro-Medusæ are very abundant in the still waters of Harrington Sound. The Echinoderms are exceedingly interesting and abundant. The Holothuria are represented by the genera *Holothuria*, *Semperia*, *Stichopus*, the last being very abundant. The Asteroidea are few and are represented by one species of *Asterias* and one of a new genus not yet determined; the Ophiuroidea by several genera. The Echinoidea are represented by *Cidaris*, *Diadema*, *Hipponœ*, *Echinometra*, *Toxopneustes*, *Mellita* and one new genus. The Crustacea are numerous and exceedingly interesting. Our collections will be studied by Dr. Rankin, who will report on them later.

The Mollusca of the archipelago number, according to Heilprin, about 170 marine forms and 30 terrestrial. Among the cephalopoda are *Octopus* and *Argonauta*. The naked *Aplysia* is fairly abundant, and, numerous other naked mollusks are found in Harrington Sound.

The Annelids are not as numerous in the places we searched as we expected, but those we found are new to us and the genera are not yet determined. The sponges are very numerous in genera and plenty in individuals. The Tunicates are exceedingly numerous and offer a rich field for investigations. *Amphioxus* is reported, but we had no opportunity to search for it. The abundance and beauty of the Bermuda fishes is notorious. Dr. Bean is making a study of them, carrying on the work started by his colleague, the late G. Brown Goode. Incidental to the main work of the expedition we undertook to furnish the Aquarium in New York with live specimens of some of these fishes, and thousands of visitors to that institution testify to their beauty and gracefulness. This part of the work was by no means the least interesting. We installed four large tanks and a pumping engine on White's Island, in the harbor of Hamilton, and acclimated the fish before transferring them to the steamship. On board the boat the fish were supplied with running water, thanks to the kindness of the Quebec Steamship Company, and no small part of our success was due to the generous and skillful aid given us by the Chief Engineer, Mr. Ritchie. Under these favorable conditions our loss was slight and another season will be much less. It is interesting to note that our efforts to bring invertebrates alive failed in every case but one, though we could keep them in prime condition until we struck the polluted waters of the coast, when they died quickly. Our failures, however, have suggested remedies, and next year we hope to show *Octopus*, *Palinurus*, *Ibacus*, *Aplysia* and the sea-anemones, as well as the fishes. The fishes thrive in the Aquarium, although the water is several degrees cooler than they are accustomed to and the salinity much less. There would be little difficulty apparently in carrying them from New York across the Atlantic, if that were desirable, under the same conditions that we carried them from Bermuda.

Our hasty survey strengthens the idea of establishing a station, and we are planning to have one in working condition by the summer of 1899, if not before. It will have two stories, the lower given up to aquaria, as at Naples, and open to the public during the winter at a small fee; the upper story will be fitted up for a laboratory, and while under the charge of the University will be open to any one competent to carry on an investigation in botany or zoology. It is not intended to rival any of the stations on the Atlantic coast, but to supplement them and to afford opportunity to investigators of America and Europe to study the flora and fauna of a tropical horizon with ease and comfort. The healthfulness of the place is attested to by the yearly visitation of over two thousand guests who spend the winter months there. Malaria is unknown, as is also prostration by heat. The climate during June and July is not disagreeable, the thermometer rarely going up beyond 82° F.

Another project in hand with the station at the Bermudas is the exploration of the West Indies with the Bermudas as a base. Two lines of steamers connect the islands with the West Indies, and the scientist starting on them equipped from the appliances of the station may make a rapid collecting trip to a desired location and return to work over his material under the more favorable conditions at the station.

New York University.

NEW DIAMOND FIND IN THE TRANSVAAL.

THE latest Johannesburg papers (*Standard and Diggers' News, Financial Record*) bring news of a very interesting and probably economically important discovery of diamonds in place, at a distance of no less than 300 miles from the mines of Kimberley and Jagersfontein. The locality is 20 miles east of Pretoria, the capital of the South African Republic, and one mile east of Merwe, a station on the railway leading to Delagoa Bay. The outcrop forms a knoll, or 'kopje,' in the Magaliesburg range. It is on the farm Rietfontein, No. 501. The first announcement of the discovery was made to the Johannesburg Geological Society by Dr. David Draper, on September 12th.

The diamonds are found in a matrix, called by Mr. G. A. F. Molengraaff, State Geologist of the Transvaal, serpentine breccia, similar in nature to kimberlite. This rock extends over a small area not yet fully explored, but known to be at least 160 feet by 250 feet, and believed to be a volcanic neck. The kimberlite is much less decomposed than at Kimberley, the yellow ground being only 5 feet in depth, and the blue ground projecting above the general level, while at Kimberley the yellow or oxidized zone extended to more than 100 feet below the surface.

Only ten 'loads' (of 16 cubic feet) of rock had been washed up to September 20th. These, however, had yielded 23 stones. Dr. Draper reports one stone of 16 carats, another of 23, and the rest smaller. The 16-carat stone is said in the *News*, of September 25th, to be a fragment broken from a larger stone, the remainder of which has not been found. The yield per load would seem to be very high, but the amount washed is too small to justify predictions, while it certainly indicates a good 'prospect.' Dr. Draper reports garnet, carbonado, olivine and 'other minerals associated with the diamond' as present in abundance. He very properly points out the likelihood that there are other diamond deposits in the neighborhood, and suggests the expediency of a search for them.

The new diamond deposit occurs in the quartzites of the Magaliesburg range, about 35 miles due north of the Main Reef Series of the Witwatersrand, at its farthest known eastern extension. The correlation of these quartzites and those along the Witwatersrand is not altogether certain. Some authorities have maintained that the Magaliesburg rocks are equivalent to the series underlying the Main Reef. Others, with better reason, as it seems to me, consider them equivalent to the Gatsrand Series which overlies the Black Reef, to the southward of the Witwatersrand. In either case they are Paleozoic, and much earlier than the coal measures of the Karoo, which are supposed to be Triassic, and which rest unconformably on the Black Reef Series. The rocks of these earlier formations contain no coal and no bituminous shales so far as is known. In this new diamond occurrence there is no apparent reason to attribute the formation of the crystals to the local effect of lava on superficial deposits of amorphous carbon. It will be interesting to ascertain whether the lava of the new locality contains a soluble hydrocarbon like that which Sir Henry Roscoe found in kimberlite.

Diamonds have not been found in the Transvaal in the original matrix until the discovery here reported. In 1893, however, diamonds are said to have been found in auriferous ore close to Klerksdorp, in the southern part of the Transvaal. The gold-bearing ore at this point is reputed to be pudding stone of the Cape formation. The diamonds, of which somewhere about a score were found, were small and of a greenish tint.* I am not aware that any

*C. S. Goldmann, South African Mining and Finance, Vol. 2, 1895–6, page 29.

further finds were made at this point. If there is no mistake about this occurrence, there must have been diamonds in this region long before the intrusion of any known mass of kimberlite.

In the Orange Free State there are a number of localities at which the diamond has been found, although Jagersfontein is the only one which has yielded this gem in important quantities. The most northerly locality in the Free State of which I have heard is at Driekopjes, in the Kroonstad district. This district is bounded on the north by the Vaal River and it lies just south of Potchefstroom district, in the Transvaal. It is to be hoped that some geologist may eventually visit all the known diamond-bearing localities in South Africa and give the world the benefit of a comparative study.

GEORGE F. BECKER.

WASHINGTON, October 31, 1897.

CURRENT NOTES ON PHYSIOGRAPHY.

THE GREAT LAKES.

GILBERT'S discussion of 'Modification of the Great Lakes by Earth Movement,' presented to the Detroit meeting of the American Association, is published in the September number of the *National Geographic Magazine* (VIII., 1897, 233–247). It is truly astonishing that in the dozen years since the tilting of the ancient lake shore lines was recognized, and in our brief half century of accurate lake levellings, quantitative results as definite as those here announced should have been reached. A change of level of 0.42 foot per 100 miles per century in a direction about S. 27° W. seems to be assured. A line at right angles to this direction, drawn through the outlet of a lake, would have no change of level. All places on the lake shore northeast of such a line, or isobase, would emerge from the lake waters; all places to the southwest would be slowly submerged. Ontario lies altogether southwest of the isobase of its outlet; and, hence, the water must be encroaching on all its shores; the estimated rise at Hamilton being six inches a century. Erie is similarly situated, and the rise at Toledo is placed at eight or nine inches per century. The outlet isobase of Huron-Michigan leaves Huron altogether on the northeast, and crosses Michigan near its middle; the water surface must, therefore, be lowered ten inches a century on the northeast side of Georgian Bay, and six inches at Mackinac; while it must rise five or six inches at Milwaukee, and nine or ten at Chicago. "Chicago has already lifted itself several feet to secure better drainage, and the time will surely come when other measures of protection are imperatively demanded." In 500 or 600 years, high stages of the lake will discharge at Chicago by the ancient outlet of glacial Lake Michigan. In 1,000 years the discharge will occur at ordinary lake stages, and after 1,500 years it will be continuous. In about 2,000 years the discharge from Lake Michigan-Huron-Erie * * * will be equally divided between the western outlet at Chicago and the eastern at Buffalo. In 2,500 years the Niagara River will have become an intermittent stream, and in 3,000 years all its water will have been diverted to the Chicago outlet, the Illinois River, the Mississippi River and the Gulf of Mexico."

THE LAVA PLATEAU OF SOUTHEASTERN WASHINGTON.

THE lava plateau of the Columbia River basin, already described by Russell (Bull. 108, U. S. G. S.) a few years ago, now receives further attention from the same author (Irrigation Papers, No. 4, U. S. G. S.). A broad flat dome, uplifted 2,000 feet over the surrounding country and well dissected, forms the Blue Mountains; so well clothed with rock waste that one is astonished to learn that they are composed of

horizontal strata of basalt. From these mountains northward towards Spokane River the surface is nearly level with a deep soil cover; but it is here and there cut by deep canyons, on whose sides the lava beds form dark cliff belts. The Snake River crosses the Blue Mountain uplift in a canyon 4,000 feet deep and fifteen miles broad. The Grande Ronde, rising in many branches in the same mountains, has excavated an intricate series of branching canyons. Here the spaces between the streams are no longer flat-topped remnants of the original plateau, but sharp-edged ridges, diversified with spires and pinnacles. This river has cut a meandering trench in the floor of a flat canyon three miles wide, indicating two partial cycles of erosion. Many special features suggest interesting physiographic problems: the gravel terraces of Snake River, that once enclosed lakes in tributary streams; the falls of the Palouse, apparently the result of recent diversion of the river to a new and shorter course to Snake River; the wandering behavior of the Walla Walla on an aggraded floor, calling for special legislation regarding its use in irrigating canals; the deep fine soil on the lava plains, here and there heaped in hills, like dunes, and everywhere producing great crops of wheat in an apparently desert region. Nothing is more remarkable than the remnants of the prelava topography, whether seen in such eminences as Steptoe butte, rising over the lavas and never buried, or revealed in Snake River canyon, where a magnificent 'shut in'* occurs as the river cuts its superposed course through a deep-buried mountain of schist. Several excellent illustrations accompany the report.

*See Science, III., 1896, 661.

HANDBOOK OF CANADA.

A Handbook of Canada, published for the British Association meeting at Toronto last summer by the Local Committee, contains an account of the physical features of the Dominion by G. M. Dawson, conveniently condensed for ready reference. Thus the interior plateau of the Cordilleran region, occupying an area of 100 by 500 miles between the Gold range on the east and the Canadian Coast range on the west, is described as a peneplain of Tertiary denudation, greatly modified by Miocene volcanic accumulations and by the excavation of valleys after elevation. Its true character as a table-land cannot be appreciated until rising high enough for the eye to range along its even sky lines. Unlike the forested mountains east and west, this plateau has a drier climate, and includes wide stretches of grass-covered hills and valleys, forming excellent cattle ranges. It appears to be be correlated with the basin areas of Cordilleran region within the United States.

W. B. Dawson describes the Canadian survey of tides and currents; stating, among other things, that the current in Belle Isle strait is tidal, with a flow nearly equal in each direction. The accepted theory of a constant inward cold current is thus proved to be unfounded and misleading.

W. M. Davis.

Harvard University.

CURRENT NOTES ON ANTHROPOLOGY.

THE ANCIENT MURMEX.

In Science, April 16th, and later in No. 1, of the *Bulletin* of the Museum of the University of Pennsylvania, I announced the identification of the classical object usually called a 'bow-puller' with the *Murmex*, fastened to the fist in pugilistic contests. This identification met with general acceptance, but a few authorities of great weight, such as Sir John Evans and Professor E. S. Morse, offered against it the cogent objection that if the implement was so used, it could scarcely fail to be repre-

sented on some of the existing remains of classical art, and that none such, so far as they knew, could be adduced.

I am glad to supply this deficiency in my argument, and thus place my identification beyond question. When in Paris, in September, I examined the galleries of ancient art in the museums of the Louvre with this in mind, and was fortunate in finding a striking and beautiful example in point. It is No. 68 in the 'Salle des Caryatides,' and is labelled 'Athlete Vainqueur au Pugilat.' Each hand is wrapped in a cestus, and each is armed with a three-pointed *Murmex,* as accurately represented in the marble as this material allows. The statue is late Greek, from Rome, and the originals of the arms are now in Rome. No more conclusive evidence of my argument could be desired.

THE GODS OF THE MAYAS.

SERIOUS students of the Mayan archæology will receive with great satisfaction the revised edition of the essay by Dr. Paul Schellhas on the figures of the gods in the Mayan manuscripts (Die Göttergestalten der Mayahandschriften, pp. 34, Dresden, Richard Bertling, 1897). It first appeared in the *Zeitschrift für Ethnologie,* 1892, but the author justly considers that the progress in this line of research called for a revision of the text. He pursues the same method as before, designating the divinities by letters, and discussing their proposed identifications as questions still open. All the important attempts in that direction are referred to, and such value assigned to them as he believes they merit. The mythological animals in the Codices are also named and figured, and their possible significations explained. The essay is dedicated to Dr. E. Förstemann, and certainly no one could be found more worthy of such a tribute.

A colored reproduction of page 11 of the Dresden Codex is given as the frontispiece, and a number of illustrations in the text render the descriptions clear to the reader.

ORIGIN AND IMPORT OF THE TOTEM.

THE institution of the Totem, or something equivalent to it, prevailed widely in savage conditions of life in both hemispheres. It has generally been considered to indicate kinship, either real or ceremonial. Miss Alice C. Fletcher, in her paper on 'The Import of the Totem,' read at the Detroit meeting, takes up the totemic bond as found among the Omahas, and argues that among them it was not primarily a tie of relationship, but a purely religious lien, which connected together individuals and groups who had received similar revelations from the gods. These joined in certain similar rites and formed societies devoted to special cults. In this manner the gentes and tribes came to be based on spiritual, not physical relationship. Although the origin was thus in one sense individual, it is recognized that a man of uncommon ability and fortune might impress the group who dwelt together with the power of his totem, that is, his vision, and this would naturally be sought after and found by his descendants. This would unite the physical and spiritual kinship.

The paper is quite original in thought and founded on close personal study of the savage mind, as is evident on every page.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

Nature for September 23d contains an account of the series of micro-photographs of polished and etched surfaces of alloys, which were exhibited by Mr. J. E. Stead at the last conversazione of the Royal Society. These photographs show in many alloys, imbedded in the eutectic or what was once the mother liquor, crystals of alloys of definite

composition. Thus in copper-tin alloys rich in tin, crystals are found of the composition (approximate) Cu Sn, Cu_3 Sn_2 and Cu_2 Sn, according to the amount of copper present, the first mentioned separating from an alloy with 2% copper. In ternary alloys it has been found possible to detect two, and sometimes three, distinctly different compounds in the same microscopic field. The study of alloys by the microscope is a field which has hardly as yet been entered upon, but it promises very valuable results.

A new method for producing artificial diamonds is described by Dr. Q. Majorana in the *Rendiconti* of the Roman Academy. Carbon, heated in the electric arc is submitted to a pressure of 5,000 atmospheres generated by the action of an explosive compound on a small piston. The mass formed, which consists chiefly of graphite and amorphous carbon, is found to contain minute crystals, which show the properties of the diamond. It thus appears possible to transform amorphous carbon into the diamond directly without the medium of a solvent, which is used in Moissan's process.

The manufacture of mosaic gold (sublimed stannic sulfid) by the sublimation of tin-amalgam, sal ammoniac and sulfur was known to the later alchemists, but the part played by the sal ammoniac in the process has been a matter of conjecture, though the old process is in use to-day. It is often possible to obtain the mosaic gold by subliming the precipitated stannic sulfid with sulfur, but unless sal ammoniac is present this method often fails. In the *Zeitschrift für angewandte Chemie* J. Lagutt clears up the reaction by showing that the chlorin of the ammonium chlorid forms with the tin the volatile tetrachlorid, which is in turn decomposed by the sulfur, giving the sublimate of mosaic gold, while the ammonium chlorid is re-formed. Ammonium bromid can be substituted for the sal ammoniac, but no other ammonium salt. The formation of the mosaic gold from the direct sublimation of stannic sulfid and sulfur is accounted for by the presence of hydrochloric acid in the stannic sulfid. If this is thoroughly washed free from hydrochloric acid no mosaic gold is found.

From the new Davy-Faraday Research Laboratory comes a solution of another of the problems of the past. In 1841 Grove described a class of metallic nitrogen compounds to which he gave the name of 'nitrogurets.' These were formed by the action of six Grove cells on a concentrated solution of ammonium chlorid, with anode of zinc, cadimum, copper, etc., and kathode of platinum. Grove supposed the deposits to be compounds of ammonium analogous to ammonium amalgam, or of nitrogen and the metals. In the *Zeitschrift für Electrochemie* Heinrich Pauli describes a repetition of the experiments carried out in the Davy-Faraday Laboratory, and shows that with zinc anode Grove's zinc nitroguret is merely metallic zinc. With copper anode the deposit is a mixture of cuprous oxid and metallic copper, and with silver anode, silver oxid or silver according to the intensity of the current.

The proposal of Carnot to determine the geological age of a fossil by the relative quantity of fluorin and phosphate present has been applied, at the request of Dubois, the discoverer of the fossil remains of *Pithecanthropus erectus*, to determine whether this interesting specimen is really Pliocene. J. M. Van Bemmelen gives an account, in the *Zeitschrift für anorganische Chemie*, of an examination of the remains of a fossil elephant found in the same stratum with the *Pithecanthropus*. He finds the ratio of fluorin to phosphate in comparison with that of apatite to be 0.53, which is very close to 0.58, that given by Carnot as

characteristic of Pliocene fossils. This is a confirmation of the geological and paleontological evidence as to the age of the fossil.

SOME time since Dr. Matteucci announced the discovery of selenium in the fumarole products of Vesuvius. He now adds, in the *Rendiconti* of the Naples Academy, bromin and iodin, found for the first time in these products, though their existence was theoretically probable.

FROM an Associated Press dispatch of October 15th, we note the following, dated Berkeley, Cal.: "Gold from silver is not an impossibility, according to Edmund O'Neill, associate professor of chemistry at the University of California."

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE AMERICAN SOCIETY OF NATURALISTS.

THE American Society of Naturalists and the affiliated societies will meet at Ithaca, N. Y., on December 28th, 29th and 30th. All the societies will assemble in Sage College at 1 p. m., on Tuesday, December 28th, when an address of welcome will be made by President Schurman. The chief meeting of the Naturalists in which the other societies join is on Wednesday afternoon, for which the following program has been arranged:

I. Reports of Committees.
II. Election of new members.
III. Appointment of Special Committees.
IV. Discussion. The Biological Problems of To-Day.

Paleontology, Professor H. F. Osborn, Columbia University.

Botany, Professor Wm. Trelease, Missouri Botanic Gardens.

Anatomy, Professor Burt G. Wilder, Cornell University.

Psychology, Professor J. McKeen Cattell, Columbia University.

Physiology, Professor Jacques Loeb, University of Chicago.

Developmental Mechanics, Professor T. H. Morgan, Bryn Mawr College.

Morphogenesis, Professor Charles B. Davenport, Harvard University.

(The time allowed each speaker will be limited to ten minutes.)

Special Papers.

In the evening there will be the business session of the Naturalists and the annual dinner of the societies, at which the President, Professor C. O. Whitman, will make an address. The Ithaca Hotel will be the headquarters, but there are many excellent boarding houses at the campus, and the University will provide a luncheon each day. The members of the local committee are: Chairman, Professor S. H. Gage; Secretary, Professor W. W. Rowlee; Professor G. C. Caldwell, Professor B. G. Wilder, Professor I. P. Roberts, Professor S. G. Williams, Professor R. S. Tarr, Professor P. A. Fish, Professor E. L. Nichols, Professor L. A. Wait, Professor E. B. Titchener, Professor G. F. Atkinson, Professor L. H. Bailey.

The officers of the Naturalists are: President, C. O. Whitman; Vice-Presidents, H. P. Bowditch, E. B. Wilson, W. P. Wilson; Secretary, H. C. Bumpus; Treasurer, John B. Smith; other members of the Executive Committee, elected from the Society-at-large, Leslie A. Lee, George H. Parker.

The other societies meeting with the Naturalists are: The Association of American Anatomists, The Association for Botanical Morphology and Physiology, The American Morphological Society, The American Physiolgical Society, The American Psychological Association, Section H. (Anthropology) of the American Association for the Advancement of Science. The New York State Science Teachers' Association will meet at Ithaca, December 30th and 31st.

GENERAL.

THE National Academy of Sciences will hold its winter meeting next week in Boston, beginning on Tuesday, November 16th.

A COPE memorial meeting will be held in the Hall of the American Philosophical Society, Philadelphia, this evening, under the auspices of institutions with which Professsor Cope was connected. Addresses on the services to science by Edward Drinker Cope will be delivered as follows: Dr. Theodore Gill, Work in Fishes, Batrachia and Reptiles; Professor Henry F.

Osborn, Work in the Mammals; Professor William B. Scott, Contributions to Geology. The following delegates have been appointed to represent the cooperating associations on this occasion: A. S. Packard, National Academy of Sciences; William H. Dall, United States Geological Survey; Theodore Gill, American Association for the Advancement of Science; Henry F. Osborn, American Museum of Natural History; E. G. Conklin, University of Pennsylvania; Harrison Allen, Academy of Natural Sciences; William B. Scott, Wagner Free Institute of Science; William Pepper, American Philosophical Society.

REV. DR. SEARLE has resigned from the directorship of the astronomical observatory of the Catholic University of America, and Mr. Alfred Doolittle has been appointed to succeed him.

DR. W. v. BEZOLD, of Berlin, was awarded, on the occasion of its jubilee celebration, the gold medal of the Prussian Meteorological Institute.

THE Royal College of Physicians, London, has conferred the Baly Medal, given every three years for research in physiology, on Professor Schäffer, of University College, London.

QUEEN VICTORIA has conferred the Jubilee Medal upon Sir George Duffey, President of the Royal College of Physicians in Ireland, and upon Sir William Thomson, President of the Royal College of Surgeons in Ireland.

THROUGH *Nature* we learn that the Reale Accademia dei Lincei has recently elected the following associates and correspondents: National associate, in the section of zoology and morphology, Professor G. B. Grassi; correspondent, in the same section, Professor G. Fano; foreign associates in mathematics, Professors H. Weber and T. Reye; in mechanics, Professor G. H. Darwin; in mathematical and physical geography, Professor F. R. Helmert; in geology and paleontology, Professor A. Gaudry; in physiology, Professors H. Kronecker and O. Schmiedeberg.

DR. FOREL, professor of psychiatry in the University of Zurich and Director of the State Asylum for the Insane, has resigned these offices, owing, it is said, to the attacks made upon him by the press for the part he has taken in combatting the use of alcohol.

SIR RUTHERFORD ALCOCK died in London on November 2d, aged eighty-eight years. He had been President of the Royal Geographical Society and had published works on geography and hygiene.

A MEETING of the general committee having in charge the arrangements for the next International Congress of Zoology was held on November 4th. It will be remembered that the Congress meets in Cambridge on August 23d under the presidency of Sir William Flower.

THE Royal Academy of Belgium offers a series of prizes for 1898, the subjects of which are published in the *Revue Scientifique*. Four questions are proposed in mathematics and the physical sciences and three in the natural sciences, for the best answers to which small prizes (600–800 francs) are offered. The essays must be presented by the first of August, 1898, and we understand that foreigners may compete, though the MSS. must be in French or Dutch. A prize of 1,000 francs for the best work in astronomy by a Belgian is also offered. Further details regarding these prizes may be obtained from the Secretary of the Academy, Palais des Académies, Brussels.

SIR JOSEPH NORMAN LOCKYER, accompanied by Dr. W. J. S. Lockyer and Mr. A. Fowler, of the Royal Astronomical Society, will leave London on December 10th for Colombo to observe the total solar eclipse of January 21, 1898.

THE success attending the recent expedition of Mr. J. B. Hatcher, of Princeton University, as reported in a recent number of SCIENCE, has led him to return to that country to continue his investigations in paleontology and geology. Mr. Hatcher will land at Punta Arenas, in the Strait of Magellan, and will proceed northward to Chubut. In addition to paleontological collections, Mr. Hatcher expects to secure collections of natural history and ethnology.

MR. F. W. W. HOWELL proposes to attempt the ascent of Mt. Everest next year, and is said to have the cooperation of the Royal Geographical Society and the government of India.

PROFESSOR LAWRENCE BRUNER, of the Uni-

versity of Nebraska, whose departure for Argentine to study the plague of locusts we at the time noted, has safely arrived and is engaged in studying methods of mitigating the plague.

THE Philadelphia museums have in working order their 'Laboratory of Tests and Technology,' to be operated in connection with the other work now being done by the Commercial Museum. The laboratory is maintained as an adjunct of the scientific department, of which Gustave Niederlien, now absent in Central America, is the chief. The work of the laboratories, however, is under the immediate direction of Dr. Louis J. Matos.

THE firm of Siemens & Halske, electrical engineers, celebrated last month the fiftieth anniversary of the foundation of the firm. The firm established a fund of 1,000,000 Marks for the benefit of its workmen and officers, and appointed a committee to consider the best use to be made of the money. Herr Wilhelm Siemens delivered a speech, dwelling upon the two guiding principles of the firm, namely, scientific research and perfection of work.

THE British government has declined to take part in the Florida Fisheries Conference, stating that, while greatly interested in the objects of the Conference, it is unable to send an official representative.

THE opening meeting and exhibition of the Röntgen Society was held in St. Martin's Town Hall on November 5th. Professor Sylvanus P. Thompson gave a presidential address.

WE learn from *Garden and Forest* that a State Forestry Society was organized at Raleigh, North Carolina, on October 21st, with fifteen members. The Society elected Mr. W. E. Petty, Carthage, President; Dr. C. A. Schenck, Biltmore, Vice-President; Professor W. W. Ashe, of the North Carolina Geological Survey, Secretary and Treasurer. The main object of the Society is to lessen forest fires in North Carolina, which are doing great injury to pine lands, especially in the southeastern part of the State, in the valley of the lower Cape Fear River. Methods of improving the condition of lumbered and deteriorated woodland will also be considered, and the re-establishment of waste and eroded agricultural lands in timber.

AT the Wagner Free Institute of Science, Philadelphia, ten weeks' courses are now being given in the evenings as follows: Mondays, Professor S. T. Wagner, 'Engineering Materials;' Tuesdays, Professor W. B. Scott, 'Historical Geology;' Wednesdays, Professor R. E. Thompson, 'History;' Thursdays, Professor G. F. Stradling, 'Magnetism;' Fridays, Professor Henry Leffmann, 'Chemistry;' Saturdays, Professor Emily G. Hunt, 'Chapters from the Life of Plants.' These courses are now in session.

AT a recent meeting of the Board of Directors of the American Chemical Society it was decided to appoint a committee of three, with Dr. Wiley as chairman, with power to take charge of a want column in the *Journal* of the Society. Members of the Society seeking positions, and, also, persons desiring to employ chemists, will be allowed a three and one-half inch advertisement free of charge.

A NEW building for the chemical laboratory of the University of Berlin is now in course of erection, at a cost of about $250,000. It will contain four large laboratories, with desks for 250 students and 25 research rooms.

A PASTEUR Institute was opened in Sofia on October 18th.

PROFESSOR WILTSHIRE has presented to the mineralogical museum of Cambridge University his collection of minerals, which includes numerous specimens of high scientific value. The zoological museum has also been enriched by the addition of a collection of polyzoa presented by Miss E. C. Jelly, and of the skeleton of an elephant seal, the gift of Sir W. L. Buller.

THE New York *Evening Post* reports that Prince Roland Bonaparte has been paying the expenses of meteorological experiments made in the upper strata of the atmosphere with a balloon presented to the Central Meteorological Bureau by M. Balaschoff.

ESSAYS in competition for the Alvarenga prize of the College of Physicians of Philadelphia must be sent to the Secretary of the College by May 1, 1898. The value of the prize is about $180 and the essay may be upon any medical subject.

THE publication of the *Academische Revue*, which has contained full news and valuable

discussions of university education in Germany, will, we regret to learn, be suspended, owing to lack of financial support. The *Hochschul-Nachrichten* will, however, be continued at a cost of 6 Marks per annum.

IN the address on behalf of the faculties of the University of Chicago at the dedication of the Yerkes Observatory, described elsewhere in the present issue, President Harper gave details regarding the cost of the equipment. There was first of all the forty-inch objective, the greatest and last work of its maker, Alvan G. Clark. This objective cost, when finished, $66,000; the equatorial mounting, and the dome and rising floor cost $55,000 and $45,000 respectively. To these there must be added, as distinct gifts, the 30-foot dome for the southeast tower which cost $7,000, the 26-foot dome and mounting of the Kenwood telescope; likewise the stellar spectrograph, constructed by Mr. J. A. Brashear, costing $3,000. Besides all these, the building with its piers for the instruments, its steam-heating plant, engines, dynamos and motors, the cost of which has been in round numbers $135,000. Acknowledgment was also made of three additional gifts which had already come to the Observatory: The grounds on which it has been built, consisting of 55 acres valued at $50,000, a contribution of Mr. John Johnston, Jr.; the instruments and equipment of the Kenwood Observatory, presented to the Yerkes Observatory by Mr. William E. Hale, and the gift of Miss Catharine Bruce, of New York City, of $7,000, for a ten-inch photographic telescope with building and dome.

MR. H. C. COOPER writes us from Heidelberg calling attention to a curious exhibition of paternalism on the part of the University. All students doing laboratory work, and even attending experimental lectures in chemistry or physics, are *required* to take out an accident insurance policy covering accidents occurring in the exercises. Students entirely disabled are to receive $500 per annum, with a corresponding allowance for lesser injuries. The risk is probably not as great as outsiders may suppose from this regulation, as the premium for lecture courses per semester is only two and a-half cents.

PROFESSOR J. A. UDDEN, of Augustana College, Rock Island, Ill., writes us that Dr. N. O. Holst, of the Geological Survey of Sweden, has lately had two years' leave of absence from his work on the Survey for the purpose of studying the new gold fields in western Australia. After leaving this southern continent he visited New Zealand, China, and Japan, and then returned by way of Canada and the United States. He has seen the ancient Australian glacial deposit which is supposed to belong to the Permian age, and he says there can be no doubt but that it is an indurated boulder-clay. Its age may possibly be somewhat later than heretofore supposed, but not so much later as to detract from the importance of its bearing on the subject of geological climate. In the semi-desert, where Dr. Holst spent most of his time, the wind did not appear to him to be of any great importance as a geological agent, although dust storms are sometimes reported from the new towns on the border of the desert. One of the Australian geologists has lately made some interesting observations on what resembles a tidal action of the ground water in the sandy region in the interior. The water rises and falls at regular daily intervals, and the oscillations appear to be too great to be explained as resulting from the daily variations in atmospheric pressure.

A CORRESPONDENT writes to the London *Times* that the site of the prehistoric Celtic lake village near Glastonbury has been further excavated since July last, under the superintendence of the discoverer, Mr. Arthur Bulleid. The sites of the dwelling are marked by mounds. One of these contained the greatest depth of clay yet found, no less than 9 feet; the accumulation of successive hearths which were found necessary as the weight of the clay gradually compressed the peat beneath. This mound contained 300 tons of clay, all of which must have been brought in their boats by the inhabitants from the neighboring hills. Under the mound was found the framework of a loom with brushwood and wattlework to form the foundation. That the inhabitants were much engaged in spinning is clear from the fact that, in addition to other things connected with the craft, no fewer than forty horn and bone carding combs

have been unearthed. The number of broken bone needles and splinters of bone found in one mound seem to indicate that it was utilized as a needle factory. Another mound was very rich in fragments of pottery and other evidences of the manufacture of hardware. As usual, very few human remains were discovered, part of the skeleton of a very young child being all that was brought to light this summer. With the exception of the cracked skulls of a few unfortunate warriors, the remains of very young children have chiefly been found in past years, Mr. Bulleid being of the opinion that these primitive people conveyed their dead to the neighboring hills for interment. Parts of three broken millstones were unearthed, and in one mound a clay oven, measuring 2 feet by 9 inches. One glass article only was brought to light this year, a blue glass bead with a wavy line of dark blue running round it. Altogether the season's work has proved very interesting, and the British Association is so well satisfied with the discoveries made from time to time that at their Toronto meeting they renewed their grant towards the excavation fund.

A MUSEUM of Natural History and Anthropology was opened at Wernigerode on July 29th. It was planned by the late Prince Otto von Wernigerode and will be named after him. The Museum contains the mineralogical collections of Count Heinrich Ernst, Councillor Jasche and Dr. Döring, the herbarium of Dr. Sporleder, the zoological collections of Dr. Müller and the anthropological collections of Dr. Augustin and Dr. Friedrich.

THE last number of the *Journal* of the Marine Biological Association of the United Kingdom contains the annual report of the Director and of the Council for 1896–97. According to the notice in *Natural Science*, the Plymouth station continues to flourish and increase in utility under the direction of Mr. Allen. The Association is also fortunate in retaining the services of Mr. Holt, for the time being, as Honorary Naturalist. The Lords Commissioners of H. M. Treasury, in granting the usual £1,000 for the year 1897–98, have made it a condition that the Association will give all the assistance in its power to the Inspectors of Irish Fisheries in investigations which they desire to be made on the habits and migrations of the mackerel visiting the Irish coast. This work has thus been begun, and the principal contribution to the new number of the *Journal* is Mr. Allen's report on the present state of knowledge with regard to the habits and migrations of the mackerel (*Scomber scomber*). Most of the other papers also have an important economic bearing. The large laboratory in the Plymouth station has been provided with a new flat tank, eight feet by five feet and eight inches deep, in which Mr. Garstang has been making observations on crustacea. The sea water supplied to the laboratory is still kept distinct from the general circulation in the show tanks, and is never returned to the laboratory tanks after it has passed through them. Experience shows that the theory of 'circulation,' as applied to aquaria, is illusory and in practice disastrous.

THE United States Department of Agriculture has issued a circular by Mr. B. E. Fernow, Chief of the Division of Forestry, on recent legislation on forest reserves. It includes an account of the federal legislation to which during the year we have frequently called attention, and to legislation in Minnesota, Wisconsin, Pennsylvania and New York. In view of the importance of the action of the New York Legislature in enlarging the Adirondack Park, it may be well to give the constitution of the Commission of Fisheries, Game and Forests, under the law of April 25, 1895. This law is a comprehensive measure in which allied interests are brought under the control of a single board. The commission consists of five members appointed by the Governor with the consent of the Senate, the term of office being five years. The President, who is designated as such by the Governor, receives a salary of $5,000 per year and traveling expenses, and devotes all his time to the work of his office. The remaining four commissioners each receive $1,000 per year and traveling expenses. The board holds at least four meetings, on designated days, each year. It has a secretary at $2,000 per year, and necessary clerical force. The duties of the board are to propagate and distribute food-fish and game; to enforce all laws for the protection of fish and game and

for the protection and preservation of the forest reserve. It has full control of the Adirondack Park and forest reserve, and is authorized to make rules for its care and safety. The commission appoints thirty-five 'fish and game protectors and foresters,' one of whom is known as chief, and two others as his assistants, the chief to have direction and control of the entire force. The chief forester receives $2,000 per year and traveling expenses; the assistant foresters $1,200 each; and the remaining foresters $500 each; all having an extra allowance for traveling expenses and each of them to receive one-half of all fines collected in actions brought upon information furnished by them.

THE Cairo correspondent of the London *Times* writes: "The crime statistics for the first three quarters of this year, compiled by the Minister of the Interior, show a gratifying diminution, which is confirmed by the registers of the Ministry of Justice. The figure has fallen from 1,493 cases in the corresponding period of 1896 to 1,143—a decrease of over 23 per cent.; and robberies with violence, which constitute the most serious class of crime in Egypt, have diminished from 476 to 287, or nearly 40 per cent. The fact that the decrease is distributed generally over the country and has occurred steadily month by month shows that it is due, not to any accidental circumstances, but to better organization and control, and indicates a real advance in the state of public security throughout the country."

UNIVERSITY AND EDUCATIONAL NEWS.

PRESIDENT MCKINLEY will deliver the oration on 'University Day,' to be observed by the University of Pennsylvania, on Washington's Birthday.

THE Association of Colleges and Preparatory Schools in the Middle States and Maryland will meet this year at Vassar College, Poughkeepsie. On November 26th and 27th Professor Ralph S. Tarr and Mr Charles C. Wilson will introduce the discussion of science in the schools, which is assigned an important place on the program.

AT the annual meeting of the Council of New York University, on November 1st, Chancellor MacCracken presented a report covering the work of the University for the past twelve years. It appears that when Dr. MacCracken first became connected with the University, in 1885, the value of its property was only about $600,000, whereas it is now nearly $2,500,000. The gifts last year amounted to more than $250,000.

THE Teachers' College, New York, shows a marked growth this year, the number of students being two hundred and forty-one, against one hundred and twenty-nine last year.

IT is expected that a Hall of Physics will be built at Syracuse University next year, the sum of $25,000 having already been subscribed for the purpose.

AT the last meeting of the Board of Trustees of the University of Alabama Mr. George S. Wilkins (Princeton) was elected professor of civil and mining engineering, and Dr. John Y. Graham (Princeton) professor of biology.

DR. FRANK K. CAMERON, late associate professor of chemistry in the Catholic University of America at Washington, has been appointed research assistant in physical chemistry in Cornell University.

DR. WARNER FITE, assistant professor of philosophy in Williams College, has been appointed to a docentship in philosophy in the University of Chicago, and Mr. A. F. Buck and Miss Jane Downey have been appointed assistants in the psychological laboratory.

THE chair of philosophy and the chaplaincy of Lehigh University have been filled by the election of the Rev. Langdon C. Stewardson, rector of St. Mark's Episcopal Church, Worcester, Mass.

DR. MAX VON FREY, of Leipzig, has been called to the chair of physiology at the University of Zurich, and Dr. George Kraus to the chair of botany in the University of Halle, as successor of Professor J. von Sachs.

DR. MAX DESSOIR has been promoted to an associate professorship of psychology in the University of Berlin, Dr. Lothar Heffter has been made associate professor of mathematics at the University at Bonn, and Dr. Brikencajer

associate professor of mathematics at the University of Krakau.

DISCUSSION AND CORRESPONDENCE.

HOW TO AVOID THE DANGERS OF FORMALIN.

TO THE EDITOR OF SCIENCE: In the issue of SCIENCE for October 22d I note a letter by Dr. Dall, of the United States National Museum, in which the use of formalin for the preservation of zoological objects for dissection is declared to be dangerous to the cuticle, to the digital neural terminals and to the eyes of the dissector.

When working with formalin my eyes and nasal passages have been affected and it seemed to me that its use might be fraught with some danger. But the effect of the gas arising from specimens and of the solutions has never given in my case such serious trouble as seems to have been given the person of whom Dr. Dall speaks. To be contrasted with the effects of the reagent in this case is the fact that formalin and formaldehyde have come to be regarded as very important germicidal disinfectants to be used in inhabited rooms, where, we are told by members of the medical profession to which Dr. Dall appeals, that their use need not endanger in any way the inhabitants. Special lamps are on the market for generating formaldehyde from wood alcohol, and to be used in just such rooms. There may also be noted an experiment performed upon a calf, in which the animal was exposed for five hours to an atmosphere containing about 2% of formaldehyde. The only noticeable effect was a slight cough and a slight watering of the eyes, both of which disappeared upon bringing the animal into fresh air. What might have happened had the animal been subjected to such an exposure daily for several weeks is a question that remains to be solved. In view of the fact that formalin seems destined to be used to a very great extent in laboratories and museums, and also in view of its having been recommended as a disinfectant to be used as noted above, experiments to determine how great an exposure eyes, cuticular organs and mucous membranes can stand without injury can have nothing less than a very great importance.

But even though the use of the reagent is as dangerous as the case of the slug dissector mentioned by Dr. Dall would lead one to think, such dangers may be obviated by taking advantage of the strong affinity formaldehyde and ammonia have for one another. In rooms where formaldehyde is used dishes of ammoniated water may be placed, and specimens preserved in formalin may be washed in ammoniated water before dissection, with the result of completely neutralizing the effects of the disinfectant or preservative.

F. C. KENYON.

WASHINGTON, D. C.

PROFESSOR CATTELL'S REVIEW OF 'SIGHT.'

I RARELY ever reply to any criticism of a work of mine. I never do so unless to explain something misunderstood. But in the case of Professor Cattell's review of 'Sight' in SCIENCE for September 24th, I feel the less hesitancy because of his generous estimate of its value. There are three points on which I wish to explain myself more fully.

1. Professor Cattell objects to my view that "the central spot is necessary to the development of the higher faculties of the mind," and asks in rejoinder: "May not the mental faculties of the born-blind be developed?" And well might he object if I implied anything so absurd. But he has entirely mistaken my meaning. Perhaps I am partly responsible for a possible ambiguity, and, therefore, thank him for drawing my attention to it. I did not mean development of the higher faculties in the *ontogeny*, but in the *phylogeny*, of man; not in the education of the *individual*, but in the origin of the *race*. Perhaps, however, I ought to have used the word *evolution* instead of development. I shall make the correction.

2. Again Professor Cattell objects to my saying: "We see things double except under certain conditions." He says: "This is bad psychology. We *learn* to see them double." Of course, we learn to consciously see them double. But if we see only what we consciously see, we see comparatively little. The phenomena of double vision lie so near the surface of consciousness that the least attention recalls them. They may be called subconscious, but we base our judgments on them all the time. Surely it is the business of psychology to bring

into clear consciousness phenomena which underlie so much of our daily conduct.

3. The last point which I wish to touch is again the much discussed question of *upright vision*. I feel like apologizing for bringing up this question again; but I am convinced that much of the difference of view is the result of misunderstanding. For example, I explain upright vision by the *law of direction*. Now, surely, Professor Cattell must misunderstand the explanation when he talks of standing on one's head and still seeing things upright as controverting that law. The law of direction explains uprightness equally well, whatever be the position of the observer. I am sure the question has been obscured and the mystery intensified by that wonderful inverted retinal image. But seeing things upright is not necessarily connected with an inverted image. It is easy to imagine an eye so constructed that the retinal image shall be upright, and yet by the law of direction the object shall also be seen upright. We probably have something like this realized in the case of insects. The compound eye of insects is so constructed of slender tubes lined with pigment that only the central rays of each radiant pencil can reach and impress the retina, all others being quenched by striking on the sides. This, as shown by the figure, would make an upright

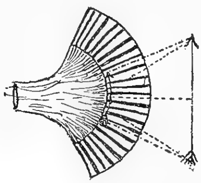

FIG. 1. Diagram showing the upright image in the eye of an insect.

image, and yet by the law of direction the object would be seen upright also. Our retina is *concave* instead of convex. It is so because the image is inverted, and, therefore, must be reinverted in the act of outward reference.

The marvellousness of the inverted image has diverted attention from the real question, which is, the seeing things in their true places. A child only a few days old will turn the eyes toward a bright light. Is there anything so mysterious in this? But why *toward*, unless it saw the light in its true direction? Now, upright vision is only a case under this more general fact; for objects are made up of an infinite number of lights or radiants and each is seen in its true direction, and, therefore, the object in its true position.

Professor Cattell refers to the recent experiments of Dr. Stratton* as controverting the law of direction, although he thinks a much easier way of doing so 'is to stand on one's head.' I am glad to have the opportunity to express my admiration of these experiments of Dr. Stratton, and my high estimate of their value; and I cannot think that the simpler mode suggested by Professor Cattell would be at all an adequate substitute. In brief, the experiment consists in the wearing of inverting glasses continually for eight days. The experimenter for that length of time never saw things except reversed. The ground was above and the sky below, things on the right were seen on the left, and *vice versa*. And yet by the end of the experiment all the movements of the body were so adjusted to the new conditions that he could walk the streets with comparative comfort.

This seems very extraordinary, and it is possible that we may have to reconstruct some of our fundamental conceptions of space; but evidently it does not controvert the law of direction. If we only think a moment, we shall see that we already have phenomena approaching in various degrees the extreme conditions of this experiment, but they are so familiar that they do not strike us with wonder. In looking in a mirror one image is *partly* inverted, *i. e.*, it is turned about a vertical axis—it is inverted from side to side, but not up and down. And yet, we easily adjust our movements to the changed conditions. We make complex movements, such as tying a cravat, with ease and accuracy.

Again, in looking through a microscope the image of the object is *completely* inverted, *i. e.*, it is turned about the visual axis 180°; and, yet, with a little practice, we adjust our movements to the new conditions. We slide the object in all directions accurately and even

* Psych. Rev. for July and September.

automatically, although to do so we must move it in a direction exactly contrary to what the image seems to require.

Now, Dr. Stratton's experiment goes one step farther. In this, not only an object, but the *whole external world*, including the visible parts of the body, are inverted. Not only some, but *all* our movements must be readjusted. The results are certainly surprising and may possibly require some reconstruction of fundamental conceptions of space—how much I am not prepared to say, but they certainly do not affect the law of direction properly understood.

The law of direction gives nothing but *the direction of the impressing force*, and this it gives always. Under *normal* conditions, *i. e.*, when the light comes straight, and without deviation from the object to the eye, it gives the true places of objects and radiants, and therefore upright vision; but not under *abnormal* conditions of deviation of the light. For example, we look at an object in a mirror inclined 45° to the line of sight. The apparent object is seen far away, 90°, from its true place; but this does not violate the law of direction, but confirms it. We see in the direction of the impressing force, which in this case—in all cases—is the *last direction of the light*. Again, in gazing at an object through a microscope, we see it inverted, *i. e.*, the radiants are seen in wrong places. But this does not violate the law of direction. We still see every radiant in the direction of the impressing force, but that direction has been changed so as to give wrong places.

So in Dr. Stratton's experiment. At first, at least, we see things in wrong places, *i. e.*, wrong as judged by the deliverances of other senses, but yet in strict accordance with the law of direction, *i. e.*, in the direction of the impressing force. As to the final result of an indefinite continuance of these experiments and whether complete accord in the deliverances of all the senses would ever be reached, so that things would again seem natural as they do now, this seems to me a question of philosophy rather than science, or, perhaps, I should say of psychology rather than physiology. I am not now concerned with it.

But it must be clearly understood that the law of direction is purely a *formal* law, *i. e.*, a law which groups consistently all the facts concerning the relative places and positions of objects in the external world *as we know it.* This is all that it pretends to do. The discovery and announcement of such general formulæ is the main function of science. As to what the external world is, and what space and direction are, that is another matter. These more ambitious questions belong to philosophy, not to science.

In conclusion, I have said that the law of direction is inherited, not acquired. By this I do not mean that in the last analysis it is not due to experience. It does, indeed, come from experience, but not mainly from *individual* experience. It is the result of *ancestral* experience, inherited all along the line of evolution ever since eyes were formed, and finally embodied in brain structure.

JOSEPH LE CONTE.

BERKELEY, October 11, 1897.

WHEN an author replies to a reviewer it is but courteous for the latter to try to show that he has not been careless in his statements.

1. Professor Le Conte's statement (page 78), "I believe that the existence of the central spot is necessary to fixed, *thoughtful attention*, and this again in its turn is necessary for the development of the higher faculties of the mind," I understood to refer both to individual development and to race evolution. The limited field of distinct vision and the associated eye-movements seem to me factors or correlates in the evolution of attention, but by no means 'necessary.' That is a dangerous word to apply to nature, which works in many ways. Most men may be 'visuals', but some of us are 'motiles'; the horse is an 'audile,' the dog an 'olefactor'. As a matter of fact, Professor Le Conte makes a mistake in stating that the 'central spot * * * exists only in man and in the higher monkeys' with a foot-note to the effect that in different forms it is found in some birds. Knox in 1823 described the central spot and fovea in lizards and they have been found in fishes by Carrière, Krause and others. A central spot, *i. e.*, an area of acute vision, has been described in nearly all mammals, though the fovea is probably only present in the pri-

mates.* Professor Le Conte maintains not only that "the fovea is necessary to the concentration of the attention on the thing looked at," but also (p. 302) that "the existence" of the fovea is determined by "the habits of the animal, especially in looking attentively."

2. I regard it as either bad psychology or bad terminology to say: "We do, indeed, see all objects double except under certain conditions." We do not hear each of the overtones of a tone because most people can learn to distinguish them, nor do we know the motives of our actions because we believe that motives exist.

3. I am glad that Professor Le Conte here calls attention to the real psychological problems involved in localization in the field of vision and in the coordination of visual and motor perceptions. The section in his book which I criticised is, however, headed 'Erect Vision,' and he writes: "How, then, with inverted retinal images, do we see objects in their right position, *i. e.*, *erect?* This question has puzzled thinkers for many centuries," etc. The question seems to me analogous to that of the child who asks how people in China with their heads down can hang on by their toes. It may be a popular paradox, but I do not admit that it is a question deserving serious scientific discussion. J. McKEEN CATTELL.

* For the most recent work on the subject cf the thesis by Dr. Slonaker in the *Journal of Morphology* XIII., 3. Professor Le Conte himself in a later chapter refers to a more highly organized central area in the lower mammals.

A SIMPLE METHOD OF COMBINING THE COLORS.

THE following very simple method of illustrating the recomposition of the spectral colors into white light has some obvious advantages in the way of ease of apprehension on the part of the beginning student. It also possesses an additional and not inconsiderable advantage in that it is striking.

A rectangular refraction tank with glass ends is set up in front of the lantern, both being preferably upon a rotating stand. From a horizontal slit a beam is projected and the prism interposed in such a manner that there is sent down into the water the rays of the spectrum, their order from red to violet running lengthwise of the tank. A few drops of milk are mixed with the water, and with care a mixture may be obtained which in a side view shows the separated rays clearly, while at the same time if viewed from the end of the tank it looks quite white. On cutting off either the violet or red end of the spectrum the end view becomes colored.

If a strong beam is available it is better to turn it back toward the lantern by a reflector before sending it through the prism. This brings the violet rays which are least intense nearest the end, where they have to traverse a thinner stratum of the mixture.

MICHIGAN COLLEGE OF MINES.

SCIENTIFIC LITERATURE.

Report of Explorations in the Labrador Peninsula along the East Main, Koksoak, Hamilton, Manicuagan and the Portions of Other Rivers in 1892–93–94–95. By A. P. LOW, B. Ap. Sc. Annual Report of Progress, Geological Survey of Canada, Vol. VIII., pp. 385.

One of the most interesting and valuable reports which has been issued by the Geological Survey of Canada in recent years has just appeared on the peninsula of Labrador, by Mr. A. P. Low.

The report embodies the results of four years' exploration, during which time Mr. Low has traversed Labrador from north to south and from east to west, and it presents in readable form a summary of our knowledge, not only of the geography and geology, but also of the climatology, botany, zoology and natural resources of this remotest part of the Dominion, the interior of which, prior to Mr. Low's exploration, was practically unknown. Mr. Low's work, the results of portions of which have been previously published in preliminary reports to the Geological Survey, and in papers presented to various scientific societies, has attracted much attention and has recently been accorded an especial recognition by the Royal Geographical Society of England. The report is accompanied by a fine map of Labrador, in four sheets, on a scale of 25 miles to the inch, which is colored geologically along the lines

of traverse, and it is illustrated by a number of views showing the character of the country, among them one of the Grand Falls of the Hamilton River, concerning which there was so much discussion a few years since.

The peninsula may be described as a high rolling plateau having a general elevation of from 1,600 to 1,800 feet, the surface sloping rapidly down towards the Atlantic and Gulf of St. Lawrence, but much more gently toward James Bay. To the north of Nain the high land of the coast rises in sharp unglaciated mountains to the height of from 2,500 to probably 6,000 feet.

One of the most remarkable physical features of the country are the deep cañons or fjords followed by all the rivers draining the interior where they cut through the margin of the peninsula and run out to sea. These have rock walls from 1,000 to 4,000 feet in height, while the river channels are from 10 to 100 fathoms deep. They appear to be valleys of deundation and are of very ancient origin, antedating the Cambrian, undisturbed horizontal beds of this age being found deposited upon their lower levels. The gorges of the Hamilton, Sandwich and Kaipokok might be cited as examples, as well as those of the Moisir and Saguenay, discharging into the Gulf of St. Lawrence.

About nine-tenths of Labrador is underlain by rocks of Laurentian age, and, like all the rest of the glaciated Laurentian country, the plateau is studded with myriads of lakes, great and small, which are estimated to occupy at least one-fourth of the total surface, and which are drained by a network of streams discharging into the deep fjords above referred to. The peninsula is underlain exclusively by the oldest rock systems of the earth's crust, the Laurentian, Huronian and Cambrian, besides certain rocks of intrusive origin. The Laurentian rocks differ in no essential particular from those found elsewhere in Canada. Both the Fundamental Gneiss and the Grenville Series are largely represented, the latter running in wide and persistent bands across the country and consisting of micaceous gneisses and schists, quartzites, crystalline limestone, etc., often holding graphite. Great anorthosite intrusions cut these rocks, and from certain of these intrusions is derived the precious labradorite.

The Huronian is represented by several widely separated areas of clastic and volcanic rocks, together with many basic eruptives. They consist of schists of various kinds, with conglomerates, breccias, diorites and other rocks. The Laurentian and Huronian are intensely folded, the folding having taken place at a time long prior to the deposition of the sedimentary beds of Cambrian Age, and a sufficiently long time had elapsed, as has been mentioned, between the period of folding and the Cambrian submergence to permit of enormous denudation and erosion.

The Cambrian strata, which rest uncomformably upon the Laurentian and Huronian, consist of bedded sandstones, argillites, shales and limestones, along with bedded traps and other volcanic rocks and enormous deposits of excellent iron ore, whose mode of occurrence is closely analogous to that of the iron ores of Michigan and Wisconsin.

The surface of the country is mantled with drift, and there is distinct evidence that the whole Labrador peninsula, except a narrow strip of very high land along the North Atlantic coast, was completely buried in ice during a portion at least of the glacial period. The movement of the ice was outward in all directions from a central gathering ground. The position of this névé field was about midway between the east and west coast of the peninsula and between latitudes 53° and 55°, and the area is now characterized by the presence of partially rounded boulders and angular blocks of rock scattered over hill and hollow. Most of these repose on rocks of the same petrographical character as themselves and have evidently been transported but very short distances from their original positions. They probably represent boulders of decomposition but slightly modified by subsequent ice action.

The various sorts of drift and the forms assumed by the drift are described, although a detailed study of these was impossible, owing to the dense forest growth which covers the greater part of the area. There is distinct evidence of a past glacial uplift, which, however, it is believed was not equal all around the coast,

being about three times as great on the south and west margins as along the north and east coast, where two hundred feet appear to be the limit of raised marine terraces and beaches. Appended to the report are lists of the mammalia, birds, food fishes and plants found in Labrador, as well as an appendix by Mr. Ferrier on the microscopical structure of some of the rocks collected, and one by Mr. Eaton on the meteorology of the peninsula.

McGILL UNIVERSITY, MONTREAL.

L' Evolution de commerce dans les diverses races humaines. Par CH. LETOURNEAU, Professeur à L' École d' Anthropologie. Paris, Vigot Freres. 1897. Pp. 581.

Professor Letourneau has made it his special branch to write about the development of arts and institutions. In the volume before us he takes up commerce, and aims to show its beginning and its growth in the various races and nations of humanity. Beginning with animals of lower species he is obliged to acknowledge that he finds no traces of commerce among them, and tells but one doubtful story of the possible interchange of values between a bird and a man.

In the lower races he discovers still little which is really commerce. When they give in exchange they appear to think each party makes a true gift to the other, and the mercantile idea is not present. Perhaps here he overlooks a peculiarity of human nature which exists in the highest as well as the lowest civilization. There is, for instance, a sort of pride which while expecting exchange on equal terms declines to recognize it as such. It is illustrated in the American custom of 'treating.'

Leaving this aside, the author pursues his investigations among the negro races of Papua and Africa, discovering in them a strong commercial instinct. In Polynesia he recognizes a widespread commerce, but his chapter on that of Ancient America is very much short of what the reader has a right to expect. The authorities whom he quotes are mostly second-hand, such as Prescott and Bancroft, and he does not seem to be acquainted with the valuable articles of Professor Rau on this topic. Hence we are not surprised to find on page 173 the assertion that the Indians considered commerce of the least possible importance; whereas, every one acquainted with the facts knows that it was one of their most active avocations.

He is more at home when dealing with the early commerce of China, Japan, Egypt and the Arabs, who next occupy his attention. Of their activity in this direction he presents a well written sketch. The classical epochs of Greece and Rome are described in their commercial relations, and from them he passes on to mediæval and modern life, of which he gives a hasty outline. His final chapter is intended to embrace the survey of his results and the forecast of what commerce may be in the future. In this prophetic utterance he indulges in some of those dreams of a possible future society with which he delights to amuse his readers, but for which he acknowledges his hopes are faint.

The work is well printed and has a carefully arranged table of contents and a sufficient index.

D. G. BRINTON.

How to Know the Shore Birds (Limicolæ) of North America. By CHARLES B. CORY. Boston, Little, Brown & Co. 1897. Small 4to. Pp. 89. Price in paper, 75 cents.

How to Know the Ducks, Geese and Swans of North America. By the same author and publisher. Pp. 95. Price in paper, $1.00.

These publications are a departure in the way of ornithological literature. Each consists of a key, with figures of heads, bills and tails, followed by plain descriptions of the species, with additional illustrations and a paragraph or two on the range and eggs. The illustrations are half-tone reproductions of wash drawings by Edward Knobel, and while not equal in artistic merit to those of Fuertes, Ridgway or Thompson are excellent for purposes of identification, and some are admirable as pictures, particularly the one of a group of Labrador ducks. In the case of the shore birds, where the beginner is often confused by strikingly different seasonal plumages, both summer and winter dress are shown; and in the case of the water birds having different sexual plumages, pictures of both male and female are given.

The keys do not conform to the modern

'dichotamous' system, now so generally and so deservedly popular. They are based primarily on length of wing, and there are usually several successive categories of equal rank. The objections to this arrangement are partly overcome by the use of very large type for the main headings.

The books are intended primarily for sportsmen and others "who are interested in birds and would like to know their names, but often find it no easy task to identify them by the 'bird books.'" That they fulfill this purpose admirably will be evident to all who use them. The paper and press work are good and the prices remarkably low.

Mr. Cory has made many contributions to ornithology, the most important of which relate to the 'Birds of the West Indies.' His entertaining 'Hunting and Fishing in Florida,' published about a year ago, gained him a wider circle of readers, but it is doubtful if any of his writings will prove so helpful to so large a class as the two that form the subject of this review.

C.H. M.

Les gaz de l'atmosphère. Par H. HENRIET. Paris, Gauthier-Villars et Fils; Masson et Cie.

This short treatise presents the reader in concise form a great deal of useful information with regard to the composition, methods of analysis, and rôle played by the various constituents, of the atmosphere. While the references to recent work would seem to indicate that the book is abreast of the times, the fact that, with few exceptions, the investigations noted are those by French scientists only is not calculated to inspire confidence in the author's conclusions. In the text, although the names of others than Frenchmen occasionally appear, there is no reference to any paper not printed in a French journal. In a bibliography whose length should guarantee its completeness, there is the title of one English book and that of one Italian memoir; the remainder are all French. On the other hand, as the book is evidently written for Frenchmen, it may be that the author gave only such references as would be readily available in almost any public library in France. On the whole, this defect will militate against the use of M. Henriet's convenient little book by others than his fellow-countrymen.

W. W. R.

Argon, a New Constituent of the Atmosphere. By LORD RAYLEIGH and PROFESSOR WILLIAM RAMSAY. Washington, The Smithsonian Institution. 1896.

This paper is published by the Smithsonian Institution in the form in which it was presented in competition for one of the Hodgkins Fund prizes. It remains but to notice that it differs from the abstract which appeared in the *Proceedings of the Royal Society*,* in that it contains detailed accounts of experiments and results omitted in many cases from the abstract; and from the fuller paper in the *Transactions*,† since the latter incorporates the results of later experiments in several directions.

It may be as well to call attention to a typographical error in the formula (p. 35) which indicates the relation between the velocity of sound in a gas and the ratio of the specific heats: 'N' should be '$\sqrt{\ }$' W. W. R.

Atmospheric Actinometry and the Actinic Constitution of the Atmosphere. By E. DUCLAUX. Washington, The Smithsonian Institution. 1896.

This paper is a translation of that presented by M. Duclaux in competition for one of the Hodgkins Fund prizes. It represents an endeavor to measure the quantity and effect of the actinic solar rays, as distinguished from the luminous and calorific, under varying atmospheric and climatic conditions.

The reagent employed for these measurements is a solution of oxalic acid; this is rapidly oxidized by actinic rays, is not affected by the luminous rays and scarcely at all by the calorific, while the reaction is but slightly exothermic. From the summary of results the following may be noted as of special interest: The 'daily combustion' varies from one day to another much more than any other meteorological phenomenon. It shows the influence of the seasons and manifestly exhibits a maximum in the

* Vol. 57, p. 265. This paper also was published in this country, *e. g.*, *American Chemical Journal*, Vol. 17, p. 225.

† Vol. 186, p. 187.

spring. It is but feebly subject to the influence of altitude. So sensitive is it to the presence of oxidizable substances in the air that daily and local variations must be due to the existence in the atmosphere of 'actinic clouds' otherwise undiscoverable. In northern latitudes the atmosphere is less absorbent of actinic rays and hence that kind of radiation is more active relatively than in lower latitudes. The actinic effect of the sun increases more rapidly than the duration of its presence above the horizon; as a result, the effect produced during the long days of the northern summer is proportionally very great. The actinic effect may continue after the luminous effect of the sun's radiation has become clouded; thus the effect of a fine morning is not lost by a dark and cloudy evening. The duration of the day and the solar effect as usually measured are of little value for calculating the true actinic effect of sunlight. The paper as a whole is of unusual interest.

SOCIETIES AND ACADEMIES.

KANSAS ACADEMY OF SCIENCE.

THE thirteenth annual meeting of the Academy was held at Baker University on October 27th, 28th and 29th, under the presidency of Professor S. W. Williston.

The scientific program was as follows:

The migrations of birds.........................J. R. Mead
A list of the Goss Ornithological Collection, being the report of the Board of Curators....D. E. Lantz
A Bibliography of Kansas ornithology, with an historical list of Kansas Birds...........D. E. Lantz
A list of the birds taken in Mexico and Central America by the late Colonel N. S. Goss, with notes of localities...........................D. E. Lantz
An historical list of Kansas mammals.......D. E. Lantz
The injurious insects of the year in Kansas......... S. J. Hunter
Kansas *Lachnosterna*.........................Warren Knaus
Entomological collecting notes...........Warren Knaus
Observations on the elm-twig girdler................ Percy J. Parrott
The natural history possibilities of Belvidere, Kansas.......................................C. N. Gould
An inexpensive dissecting-stand for microscopical dissections.................................S. J. Hunter
Biological notes................................S. J. Hunter
A floral horologue for Kansas..............B. B. Smyth
Root tubercles and their production by inoculation..D. H. Otis
Therapeutical notes on some Kansas plants......... L. E. Sayre
Notes on Kansas plants..................A. S. Hitchcock
Bibliography of literature relating to wind effects on trees.................................J. B. S. Norton
On the finding of insects in the Comanche Cretaceous of Kansas............................C. N. Gould
Fusulina cylindrica shell structure........Alva J. Smith
Range and distribution of the *Mosasauria*.......... S. W. Williston
A new *Labyrinthodont* from the Kansas Carboniferous..................................S. W. Williston
Geological notes on Trego County and vicinity J. W. Beede
A preliminary report on the geology of the Delaware Valley in Atchison County.....J. W. Wilson
New developments in the Mentor beds...C. N. Gould
Extremes and means of Kansas climate....F. H. Snow
Viscosity of the ether...................A. St. C. Dunstan
Alternating currents in a Wheatstone bridge where branches contain resistance and capacities.......................................Martin E. Rice
Equilibrium of forces in a flim originally spherical, grounded in the presence of an external electric charge...............................L. I. Blake
Some problems of marine telephony without wires...L. I. Blake
The dehydration of gypsite...............E. H. S. Bailey
Some new mineral waters.................E. H. S. Bailey
Decomposition of some diazo compounds with methyl alcohol..........................Geo. F. Weida
On the generation of finite transformations from infinitesmal transformations..........H. B. Newson
Additional notes on the timbered mounds of the Kaw Reservation..........................C. N. Gould
Relativity in science............................E. B. Knerr

The subject of the President's address was 'Science and Education.'

*THE IMPORTANCE OF ASTROPHYSICAL RESEARCH AND THE RELATION OF ASTROPHYSICS TO OTHER PHYSICAL SCIENCES**

THE domains of the physical sciences are not, like the political divisions represented on a map, capable of being defined by boundary lines traced with mathematical precision. They pass into one another by imperceptible gradations, the unity of nature opposing itself to rigid systems of classification. Thus there often exists between two allied sciences a broad ground, belonging to each, yet exclusively the property of neither, which may be so extensive and fertile as to justify the development of a new science for its special cultivation. And such a science not only subserves the purpose for which it was created, but it has the further special importance that, by promoting an exchange of knowledge between its previously established neighbors, by investigating the cause of disagreements between them, by comparing their methods, and possibly by detecting errors in their results, it tends to bring them into more perfect coordination.

Such is the nature of the science which Professor Langley has called the new astronomy, and which is also, and perhaps more generally, known as astrophysics. Its

*Address delivered at the dedicatory exercises of the Yerkes Astronomical Observatory, of the University of Chicago, Williams Bay, Wis., Thursday, October 21, 1897.

high development has in fact been so recent that its name is found in only our latest dictionaries. It is closely allied on the one hand to astronomy, of which it may properly be classed as a branch, and on the other hand to chemistry and physics; but it assumes wide privileges, and it is ready to draw material which it can use with profit, from any source, however distant. It seeks to ascertain the nature of the heavenly bodies, rather than their positions or motions in space—*what* they are, rather than *where* they are; and for my own convenience I shall use the terms astrophysics and astronomy to denote the sciences of which these aims are respectively characteristic. Yet here again the line of demarcation cannot be sharply drawn, since the measurement of celestial motions that cannot be dealt with by the methods of the older astronomy is one of the most important tasks of the astrophysicist. That which perhaps is most characteristic of astrophysics is the special prominence which it gives to the study of radiation. The complex nature of white light, in particular, is never lost sight of, and its consequences are thoroughly exploited.

That the older astronomers made no efforts systematically to study the nature of the heavenly bodies, is to be ascribed to the seeming hopelessness of such an attempt in their day, rather than to a lack of interest in the subject, or a slight appreciation of its importance, on their part. They did, in fact, seek explanations of such phenomena as they could observe, and the beginnings of astrophysics are to be found far back in the past. But the curious speculations of Sir John Herschel on the structure of the sun's photosphere show how inadequate was the supply of facts to serve as a basis for a science of solar physics in Herschel's time. The conception of living organisms a thousand miles long, floating about on the sun's surface, and shining with the intense brilliancy of the photosphere, seems to us extraordinary, and even grotesque. To lose its strangeness it has to be considered with reference to the contemporary state of knowledge. But the fact that only fifty years ago it was regarded as an admissible supposition by one of the most eminent of astronomers helps us to realize how rapid has been the advance of astrophysical science. It was only after the discovery was made, that the light which reveals to us the existence of the heavenly bodies also bears the secret of their constitution and physical condition, that the basis for a real science was obtained. The spectroscope placed new and hitherto undreamed-of powers in the hands of men. It is to the astrophysicist what the graduated circle and the telescope are to the astronomer.

The study of astrophysics does not at present seem to have a very direct bearing on the practical affairs of everyday life. If to this statement the objection should be made that the study of solar radiation is likely to lead to a practical method of utilizing the sun's heat as a source of mechanical power, I should say that such a discovery (if it is ever made) is much more likely to be the result of an ingenious application of principles already known. What the future may have in store we cannot tell, but at present the statement I have made holds good. With respect to practical usefulness, therefore, astrophysics does not possess the same claims to consideration as astronomy, which has obviously important applications in furnishing standards of time, and in surveying, geodesy and navigation, and in addition to these, an immense indirect influence on thousands of ordinary affairs. Yet on such grounds it is not probable that any astronomer would care to base a claim for his science. Astronomy long ago reached that state of perfection which suffices for the practical ends

I have mentioned, and is still pursued with undiminished vigor. Both astronomy and astrophysics take their stand on a higher plane, where it is a sufficient justification for their existence that they enable us better to understand the universe of which we form a part, and that they elevate the thoughts and ennoble the minds of men.

In considering the importance of astrophysical research, I have, therefore, regarded the question from a purely scientific point of view. Even with this restriction there is room for a considerable diversity of opinion, since the elimination of the human element from the question is impossible. Scientists are men. Every man is naturally inclined to attach special importance to that in which he is himself specially interested. Personal preferences, or even prejudices, may enter into the estimation in which a branch of learning is held. But, setting these aside, there are grounds for differences of opinion which are entitled to respect. What importance is to be attached, for example, to the proof, now brought almost within our grasp by the improvement of spectroscopic instruments and methods, that the law of gravity is operative within the stellar systems, as well as in the system of our own sun? Doubtless there are some who are satisfied with the moral certainty that we already possess, and to whom the proof just mentioned would merely afford the satisfaction of inking in, on a printed form, the penciled words which had already been written in its blanks; while there are others who would regard the formal proof as alone entitled to consideration. I have even heard widely different opinions expressed by eminent astronomers as to the scientific importance of a problem so fundamental as the exact determination of the distance of the sun.

The degree of importance which we attach to a newly discovered fact or principle is influenced by many circumstances, among which we cannot fail to recognize some of the failings of human nature. When progress is rapid, individual achievements lose their prominence, like mountain peaks rising from a high plateau. The discovery of an asteroid was once a notable event. Now it attracts little attention, outside of a small circle of observers, and it is probable that few of us could say just how many of these little bodies have been brought to light during the past year. In astrophysics discoveries of the highest significance have succeeded one another so rapidly that they are now taken as a matter of course.

The bearings of a discovery on existing knowledge are sometimes not immediately perceived, and its true scientific importance is not appreciated until these are revealed in the fullness of time. Other circumstances might be mentioned, but these are sufficient for my purpose, which is to show that there is no cause for surprise if opinions differ as to the exact value of astrophysical research. It is because the science of astrophysics is so young—so distinctly in the formative stage—that I have ventured to discuss a question which, in due time, will settle itself.

A feature of astrophysical research which I do not wish to leave unmentioned is the interest which is felt in it by the public. Those who are interested in the results of science, but who care little for methods, and know nothing of elegant forms of analysis, are naturally more attracted by the view of the heavenly bodies which astrophysics presents than by the view which is obtained from the standpoint of the older astronomy. Astrophysics paints its picture in the brighter colors. A star regarded as a center of attraction, or as a reference point from which to measure celestial motions, awakens little enthusiasm in the popular mind; but a star regarded as a sun, pouring out floods of light and

heat as a consequence of its own contraction, torn by conflicting currents and fiery eruptions, shrouded in absorbing vapors or perhaps in vast masses of flame, appeals at once to the popular imagination. Both branches of astronomy share in the advantages which follow this awakening of popular interest; for that popular interest in any science is to be deprecated is to my mind utterly inadmissible. The cultivation of a pure science is possible only in those communities where such an intelligent interest exists. Without it we should not be here to-day. It is splendidly manifest around us. The only possible danger to be feared is that interest in results whose significance is readily understood may lead to an undervaluation by the public of results which are of the highest importance, but which only the trained specialist can fully comprehend; and this danger will be avoided if scientific men publicly express their own appreciation of results which belong to the latter class.

Popular interest which is not of this character, but which has no purpose other than amusement, is less desirable. "It is the universal law," says Macaulay, "that whatever pursuit, whatever doctrine, becomes fashionable, shall lose a portion of that dignity which it had possessed while it was confined to a small but earnest minority, and was loved for its own sake alone." Macaulay is here referring to a temporary interest in scientific matters which prevailed among fashionable circles in the reign of Charles the Second—to what would now be called a 'fad.' In our own time science occasionally suffers in much the same way. It is to be regretted that the habitability of the planets, a subject of which astronomers profess to know little, has been chosen as a theme for exploitation by the romancer, to whom the step from habitability to inhabitants is a very short one. The result of his ingenuity is that fact and fancy become inextricably tangled in the mind of the ay man, who learns to regard communication with the inhabitants of Mars as a subject deserving serious consideration (for which he may even wish to give money to scientific societies), and who does not know that it is condemned as a vagary by the very men whose labors have excited the imagination of the novelist. When he is made to understand the true state of our knowledge of these subjects he is much disappointed, and feels a certain resentment towards science, as if it had imposed upon him.

Science is not responsible for these erroneous ideas, which, having no solid basis, gradually die out and are forgotten. Thus it cannot long suffer from outside misapprehension, while the sustained effort necessary to real progress is in the end a sufficient safeguard against the intrusion of triflers into its workshops.

In astrophysics sustained effort is as necessary as it is in other branches of science. There is an impression in some quarters that the results of astrophysical investigation are easily obtained. That this is in some cases true may readily be admitted. I cannot regard it as a reproach. It is one of the advantages to which I have referred by bringing new methods to bear on old problems. What an effort to grasp something tangible we observe in the earlier writing on Fermat's principle! What a groping in the dark after a principle felt rather than seen! and how obvious the same principle is from the point of view of the wave theory! In a field so wide and so little explored as astrophysics there must be novelties which can be gathered with comparatively little effort, and which may nevertheless be of no small importance. But there are also problems whose solution calls for the exercise of the highest intellectual faculties, and for the most strenuous exertion.

In astrophysics difficulties are met with

quite different from those of physical astronomy. There a vast variety of highly complex phenomena are to be referred to the operation of a well-known and extremely simple law. The mental discipline there obtained is of the highest order, and it is hardly necessary to say that a training in the methods of the older astronomy should be regarded as an indispensable preparation for astrophysical work. But in astrophysics, as in the sciences of chemistry and biology, there are difficulties which arise from an imperfect knowledge of the laws governing the phenomena observed. The discovery of unknown laws and principles, as well as the explanation of phenomena by laws already known, is one of its most important objects.

I have referred to the differences of opinion which usually exist with reference to the value of a new science. There may be some who view with disfavor the array of chemical, physical and electrical appliances crowded around the modern telescope, and who look back to the observatory of the past as to a classic temple whose severe beauty had not yet been marred by modern trappings. So mankind, dissatisfied with present social conditions, looks back with tender regret to the good old times of earlier generations, yet rushes forward with the utmost speed. May we regard the eagerness of pursuit as a measure of the value of its object? That the importance of astrophysical research, considered with respect both to its own ends and to its bearing on the advance of knowledge in other fields, is already great, and that it will grow steadily from year to year, is naturally my own belief. In a general way I have considered some of the reasons on which it is founded, and I now wish to call your attention to a few specific cases which illustrate my general remarks, and in which I think the importance of astrophysical science is manifest.

Some of the most noteworthy advances in astronomy and in astrophysics have been made possible by the introduction of photography. The photographic plate not only gives a permanent record of what the eye can see, but, by its integrating power continued through long exposures, it builds up a picture from light impulses too feeble to affect the sense of vision. Thus it has been discovered that vast regions in the sky are filled with diffuse nebulæ, which (since the apparent brightness of a surface cannot be increased by any optical device) must ever remain unseen. This information, which the photographic plate alone could furnish, is itself most wonderful and suggestive. It is, however, but a part of what the same plate may yield. Whoever has studied Professor Barnard's admirable pictures of the Milky Way in Scorpio must have observed how accurately the distribution of the smallest stars corresponds to that of the extended nebulosity which fills this part of the sky, and at the same time how strikingly the nebulous matter is concentrated around the brightest stars in the constellation. Bright stars, faint stars and nebulosity are unmistakably physically related, and, hence, at the same order of distance from the earth; and from this it follows that the real sizes of the stars are of entirely different orders. Here is a fact having a most important bearing on the question of stellar distribution, brought out by the simplest possible means. It is perhaps beyond the reach of more elaborate methods. And in this case it is to be observed that the evidence would not be made clearer by any further treatment of the material. The positions of the stars and the density of the nebulosity might be measured, and the results might be tabulated, but all to no purpose; for, if the data yielded by observation were in the form of measurements, the first step toward their interpretation would be the construction of just such a

chart as the photograph places ready in our hands.

Of very great importance to the new astronomy has been the investigation of the conditions of maximum efficiency of its chief instrument, the spectroscope, by the methods of physical optics. The theory of resolving power, introduced by Lord Rayleigh, and quite recently elaborated by Professor Wadsworth, has been especially fruitful. It has done away with the old idea that the efficiency of a spectroscope is measured by its dispersion, and may be trusted to destroy in time some musty traditions concerning the magnifying power and definition of astronomical telescopes. The theory has also been extended so as to include the spectrograph, in which the photographic plate takes the place of the eye at the observing telescope of the spectroscope. The designing of spectroscopes has thus been placed on a thoroughly scientific basis. At the same time the demands for accuracy in the practical construction of the instrument have been greatly raised. The objectives, the prisms, the fitting of the mechanical parts, must be the best possible. Hence the spectroscope has become an instrument of precision, worthy of a place among the most refined instruments of practical astronomy, and fitted for the class of work now most needed in astrophysical research.

A familiar example of the mutual obligations of allied sciences is found in the first measurements of the velocity of light. Perhaps a somewhat parallel case may have to be recorded by the future historian of science. Spectroscopists have tested the validity of what is known as Doppler's principle, by which the motion of a body in the line of sight is determined from the observed displacement of its spectral lines, and have at the same time proved the capabilities of their instruments, by means of the velocities of the earth and heavenly bodies furnished to them by astronomy. It is not impossible that this also is a reversible process, and that measurements of the velocities of bodies in the solar system may give one of the best methods of determining the dimensions of their orbits.

Numerous cases could be mentioned in which astrophysical investigations have contributed to our knowledge of the chemical elements. Of these the first which naturally presents itself is one of the most recent. The element helium was discovered first in the sun (as its name implies), then in the stars, then in the nebulæ, and at last, by Professor Ramsay, it was 'run to earth.' It had an important place in celestial chemistry long before it was known to terrestrial science; and, on account of its rare occurrence and seeming inertness, it is quite possible that but for the spectroscope of the astrophysicist we should have remained forever ignorant of its existence. To the astrophysicist, however, it was known only by the occurrence in its spectrum of one bright line. Laboratory investigations soon revealed its complete spectrum, and then the astrophysicists were able to recognize, as belonging to helium, a large number of lines whose origin in the heavenly bodies they had been unable to discover. Our knowledge of the heavenly bodies may be greatly advanced when the properties of this remarkable element shall have been thoroughly studied.

It is not necessary, however, to seek illustrations in new elements. The complete series of hydrogen lines, to which belong the few lines that are ordinarily seen in the laboratory spectroscope, was discovered by Huggins in the spectra of the white stars; and a new series, which had previously been seen by the eye of theory only, and which, so far as I know, has not yet been produced artificially, has recently been found by Pickering in the spectrum of the star *Zeta Puppis*.

Another familiar element is calcium. Its

ordinary properties are well understood. But under the conditions met with in the sun and stars it behaves in a mysterious manner. Notwithstanding its considerable atomic weight, it floats quietly high above the surface of the sun, where other heavy metals are only occasionally present in consequence of violent eruptions. It is true that the apparently abnormal spectrum of calcium under these conditions has been shown by Sir William and Lady Huggins to be merely the result of extreme tenuity of the luminous vapor; but the existence of calcium at such great heights, under any conditions whatsoever, seems to point to some remarkable property of the element which is unrecognizable by the methods of ordinary chemistry.

The spectrum of a substance is not the same under all circumstances. In some cases a change occurs suddenly when certain critical conditions are reached; in others the change is gradual and progressive. By studying these changes in laboratory experiments, and comparing them with what we see in the observatory, we are able to arrive at some definite conclusions respecting the conditions which prevail in the stars, while the same comparison often throws light on the phenomena observed in the laboratory. It has been shown, for instance, that the spectrum of magnesium gives a means of estimating the temperatures of the stars; and the same criterion enables us to recognize in the stars temperatures vastly exceeding the highest that have been produced on the earth. Thus the science of astrophysics allows us to extend our investigations to temperatures which the resources of the laboratory cannot furnish.

It may be well to mention an example of the difficulties, to which I have referred, arising from our imperfect knowledge of the laws which underlie phenomena constantly observed. Recent comparisons of the spectra of the sun and metals, made at the Johns Hopkins University with the concave grating spectroscope of Professor Rowland, have proved that spectral lines may not merely be widened by increased pressure of the radiating vapor, but that they may be shifted bodily; while the still more recent investigations of Zeeman show that a line may be widened (and at the same time doubled) under the influence of a strong magnetic field. It is true that in both cases the effect produced is very small. It could not lead to mistakes in identifying stellar lines, or to appreciable errors in measuring celestial motions. But the fact that the spectrum of a substance varies according to circumstances which are as yet only imperfectly understood, shows us the necessity of exercising caution in interpreting the spectral phenomena presented to us by the heavenly bodies. At present these spectral variations increase the difficulties that the astrophysicist has to contend with. Eventually they will become additional and most valuable sources of information.

The discovery, by Kayser and Runge, of line series in the spectra of the common elements has a most important bearing on the work of the astrophysicist. It provides him with the means, long greatly needed, of deciding with certainty whether or not lines in celestial spectra are identical with lines in the spectra of terrestrial substances. On the other hand, as we have already seen, he is sometimes able to supply the physicist with missing data.

From the point of view of the old astronomy the most important result of the introduction of the new methods has been the determination of motions in the line of sight by means of the spectroscope. The method has been tested so often, and with such uniform success, that there is no longer any doubt as to the correctness of the principle on which it is based, or to the accuracy of the results which it is capable of yielding

in competent hands. It is directly applicable to one of the great problems of astronomy—the determination of the direction and rate of the sun's drift through space. From the proper motions of the the stars, furnished by the methods of the older astronomy, the direction of the sun's motion can be deduced, and, under certain assumptions as to the stars' distances, the rate of motion; but it is evident that the latter element of the problem must be subject to very considerable uncertainty. With the spectroscope velocities are directly measured in miles per second. The two methods may be combined. It is probable that the most accurate determination of the *direction* of the sun's drift can be obtained by preparing proper motions, while the most accurate value of the *velocity* is that given by the spectroscope. Thus by the coöperation of the two branches of astronomy, there is measured in space a base line of constantly increasing length for a great sidereal triangulation. At present the material afforded by spectroscopic observation is not sufficient for this great work. The observations must be treated statistically, and statistical methods can be applied successfully to only a large mass of data. What is now needed, therefore, is observations of more stars, *i. e.*, fainter stars, and the German government is building a large telescope for the observatory at Potsdam (where photography was first applied to this class of observations), in order that the work may be continued. There is room, however, for the employment of other large telescopes in the same field. The multiplication of observations for this purpose is no more to be deprecated than the multiplication of observations for the exact determination of star places.

Solar physics, from which the wider science of astrophysics has been evolved, offers problems so numerous and so complicated that I cannot even mention them, still less enter into a discussion of their bearing on other branches of knowledge. And what can I possibly say of their importance? The sun is to us the grandest of material objects. It is the source of practically all our light and heat; of practically all our mechanical power; absolutely the support of all our lives. What wonder that we seek for knowledge of its nature by all the ways that we can find! These ways are opened through astrophysical research. In few of the inquiries that I have referred to can the method of light analysis be dispensed with. In most of them it offers the only chance of success.

I have time to mention only one new method of solar research. The most notable contribution to solar physics within the last few years has been the invention of the spectroheliograph by Hale and Deslandres. With this instrument photographs of the sun are taken by strictly monochromatic light, which may be chosen from any part of the spectrum. If the part selected is the middle of the K line, the picture essentially represents the distribution of calcium vapor on the disk of the sun, and the presence of other elements is ignored. This is, in fact, the line usually chosen, partly on account of the conspicuous rôle played by calcium in solar phenomena, and partly for other reasons, which it is not necessary to state. The possibilities of the method are obvious. By an ingenious modification of his instrument Hale now photographs on a single plate the Sun covered with all its spots and faculæ, and surrounded by all its prominences; and all this is done in a few minutes, in full daylight! Could the corona be added, the triumph would be complete; but the corona yet remains unconquered in its stronghold, though the attack is being vigorously pushed.

No branch of observational astronomy seems to be in so backward a state as the

representation of the surface features of the planets. Although the moon has been photographed with splendid success, and the planets with results that are encouraging and suggestive, we still rely (in the case of the planets) on the old method of hand drawing used by Galileo. The fallibility of the draftsman is well known. It has been illustrated again and again. Yet there seems to be a curious habit among some observers of regarding a drawing, when once made, as invested with high authority —as that of a standard established by legislative act. A photograph, if it could be made, would be free from the errors of the draftsman, and from a personality which is recognizable in all hand drawings, and which, though it is scarcely to be classed as an error, it would be desirable to avoid. Here, then, is another opportunity for the new methods. There is no reason to suppose that it is impossible to obtain photographs of the planets which will show all that the eye can see, although there are many reasons to know that it will be very difficult to do so. The instruments for this purpose would have to be quite different from those in general use, and there would be few occasions, in even the most favored regions of the earth, when they could be employed. Difficulties would also arise from the rapid rotation of some of the planets. But this is not the place to discuss the necessary conditions. It is only fair to say that Professor Schaeberle, of the Lick Observatory, has already been experimenting in this direction—with what success is not yet generally known.

Passing to stellar spectroscopy, a field broader even than that of solar physics is opened before us; for the sun, although paramount in his own system, is only one of the stars. In a general way, the spectra of the stars have been observed, and classified according to their character, and objects of unusual interest have been noted for future investigation—many a rare specimen has been meshed in Harvard's widely extended net; but the detailed study of individual spectra has just begun. For this purpose large telescopes are desirable, if not absolutely necessary. Many observations of precision required in the older astronomy are best made with small telescopes. But in stellar spectroscopy light is all-important; and while much can doubtless be accomplished with small telescopes, there is probably nothing that cannot be done better with large ones. Even in solar spectroscopy, where the supply of light is abundant, a large image is required for the study of individual parts of the sun's surface.

No department of astrophysics has profited more by the introduction of photographic processes than stellar spectroscopy. To the advantages of photography already mentioned there is here to be added another not less important. Owing to atmospheric disturbances the image of a star dances about on the slit-plate of a spectroscope placed in the focus of a telescope. The spectrum is not only faint, but tremulous, and to measure the lines in it by visual observation is like trying to read a printed page irregularly illuminated by flashes of light. These irregularities do not appear on the photograph. They disappear in the process of integration. Negatives obtained with the spectrograph can be directly measured under a microscope, or enlargements can be made from them in the usual manner. In this way photographs of star spectra are now made which are comparable, with respect to accuracy and wealth of detail, to Kirchhoff's famous map of the solar spectrum. "It is simply amazing," says Professor Young, with reference to the Draper memorial photographs, "that the feeble, twinkling light of a star can be made to produce such an autographic record of substance and condition of the inconceivable distant luminary."

Let us consider for a moment some of the questions in this field that are open for investigation. The motions in the line of sight of all stars within reach of the largest telescopes have to be measured. This important line of research has already been referred to. The relation has to be ascertained between the various classes of star spectra and the probable order of stellar evolution. It now appears practically certain that all the stars are not made according to a single pattern, and that they cannot be fitted into a single scheme of development. The Wolf-Rayet stars, the stars with banded spectra, the stars with bright-line spectra, the planetary nebulæ, the spectroscopic binaries, the variable stars, require the most careful attention. Variables of the Mira class should be followed with the spectroscope as far as possible from their maximum, and the spectral changes which accompany the light variation of other stars, whether due to phenomena of emission and absorption, or to relative motion of bodies in a revolving system, should be studied with the most powerful instruments.

The discovery, by means of the spectroscope, of binary stars which are far too close for resolution with our most powerful telescopes, and which are recognized in their true character by a periodic doubling of their spectral lines, has brought to our knowledge strange and wonderful conditions of orbital motion. Such a system as that of Spica, where two bodies like our sun revolve around each other like the balls of a gigantic pendulum, in a period of only four days, at a distance no greater than that which separates the sixth satellite of Saturn from its primary, must have remained forever unknown to the older astronomy. Between these spectroscopic binaries and the most rapidly revolving doubles visible in the telescope there is a wide gap, the cause of which is obvious. The conditions favorable to discovery in the two cases are directly opposed, and doubtless a large class of stars lies at present just beyond the reach of either method.

But this gap may be bridged over by means of such a great telescope as we see before us to-day, while the work necessary to accomplish this end will open up still another field for research. It has long been recognized that the position micrometer and the spectroscope, taken together, are theoretically competent to determine the real orbits in space of the components of a double star; hence, also, the masses of the components and their distance from the earth. Until recently the question had only a mathematical interest. But the small velocities to be expected in the case of any double star whose components can be separately distinguished with the telescope are now almost, if not quite, within reach of the spectroscope, and the investigation of such doubles has acquired a physical interest.

Here I must close my review of the important questions before the astrophysicist, with the consciousness that it is most remarkable for what it leaves unnoticed. I have said nothing of questions relating to the photography of comets and their spectra, the rotation of the planets or the absorption spectra of their atmospheres, the colors of double stars, the spectra of temporary stars, the measurement of obscure wavelengths; nothing about stellar photometry, the application of interference methods to spectroscopic research, the exploration of the infra-red spectrum. But I will not trespass further on your patience. In all the fields that I have mentioned there are noble problems, worthy of the best efforts that can be given to their solution. To realize their importance, think how ill we could spare what we have already won. What a blank would be left in our knowledge of the heavens if the results of astro-

physical research in our own generation were stricken out!

The future should look bright, indeed, as we view it to-day. Munificence and skill have provided this splendid observatory with means for promoting knowledge in both the older and the newer branches of the sublime science to which it is dedicated. Its magnificent equipment will be used by men who have won merited distinction in both the older and the newer methods of research. It has the cooperation and support of a great institution of learning. From this happy union of ability and opportunity we have reason to expect results of the highest import to the new astromony, and to its allied branches of physical science.

But, lest any words of mine should give rise to expectations that may not be fulfilled, I wish to say once more that important results are not necessarily of a striking or surprising character. We can hardly assume that every increase in telescopic power will be followed by the discovery of new planets or satellites. Such discoveries, if they come, will be welcome; but they should not be expected. There may be no more planets or satellites, yet undiscovered, in the solar system. But we may confidently expect from the work of this observatory those results which throw light on the dark places in nature, and which, therefore, though they may not stimulate the popular imagination, are of the very highest importance, for they are indispensable to true scientific progress.

JAMES E. KEELER.

ALLEGHENY OBSERVATORY.

MATHEMATICS AND ASTRONOMY AT THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE officers of the Section of Mathematics and Astronomy were as follows: Chairman, W. W. Beman; Secretary, J. McMahon; Press Secretary, P. A. Lambert; Councillor, E. W. Hyde; Sectional Committee, W. W. Beman, J. McMahon, A. Macfarlane, W. F. Durand, J. E. Kershner, W. S. Pritchett; Member of Nominating Committee, A. Ziwet; Committee to nominate officers of Section, W. W. Beman, J. McMahon, A. Hall, Jr., R. S. Woodward, A. Macfarlane.

The Chairman's address was on 'A Chapter in the History of Mathematics,' which has already been published in this JOURNAL.

The following papers were presented to the Section:

1. A Problem in Substitution-groups. By Dr. G. A. Miller, Rosette, Kan.

2. Continuous Groups of Spherical Transformations in Space. By Professor H. B. Newson, Lawrence, Kan.

3. The Treatment of Differential Equations by Approximate Methods. By Professor W. F. Durand, Ithaca, N. Y.

4. Commutative Matrices. By Professor J. B. Shaw, Jacksonville, Ill.

5. On the Theory of the Quadratic Equation. By Professor A. Macfarlane, Lehigh University, South Bethlehem, Pa.

6. A New Principle in Solving Certain Linear Differential Equations that occur in Mathematical Physics. By Professor A. Macfarlane, Lehigh University, South Bethlehem, Pa.

7. Condition that the Line Common to $n-1$ Planes in an n-space may Pierce a Given Quadric Surface in the Same Space. By Dr. Virgil Snyder, Ithaca, N. Y.

8. The Psychology of the Personal Equation. By Professor T. H. Safford, Williamstown, Mass.

9. Compound Determinants. (Preliminary communication.) By Professor W. H. Metzler, Syracuse, N. Y.

10. Waters within the Earth and Laws of Rainflow. By W. S. Auchincloss, C.E., Philadelphia, Pa.

11. On the Secular Motion of the Earth's Magnetic Axis. By Dr. L. A. Bauer, University of Cincinnati, Cincinnati, O.

12. Simple expressions for the Diurnal range of the Magnetic Declination and of the Magnetic Inclination. By Dr. L. A. Bauer, University of Cincinnati, Cincinnati, Ohio.

13. The Theory of Perturbations and Lie's Theory of Contact-transformations. By Dr. E. O. Lovett, Princeton, N. J.

14. On Rational Right Triangles. No. I. By Dr. Artemas Martin, U. S. Coast Survey, Washington, D. C.

15. Some Results in Integration expressed by the Elliptic Integrals. By Professor James McMahon, Cornell University, Ithaca, N. Y.

16. Modification of the Eulerian Cycle due to Inequality of the Equatorial Moments of Inertia of the Earth. By Professor R. S. Woodward, Columbia University, New York.

17. Integration of the Equations of Rotation of a Non-rigid Mass for the case of Equal Principal Moments of Inertia. By Professor R. S. Woodward, Columbia University, New York.

18. General Theorems concerning a certain class of Functions deduced from the properties of the Newtonian Potential Function. By Dr. J. W. Glover, Ann Arbor, Mich.

19. The Importance of adopting Standard Systems of Notation and Coordinates in Mathematics and Physics. By Professor Frank H. Bigelow, U. S. Weather Bureau, Washington, D. D.

20. A Remarkable Complete Quadrilateral among the Pascal Lines of an Inscribed Six-point of a Conic. By Professor R. D. Bohannan, Columbus, Ohio.

21. Stereoscopic Views of Spherical Catenaries and Gyroscopic Curves. By Professor A. G. Greenhill, Royal Artillery College, Woolwich.

No. 1 pointed out that to every simple isomorphism of a group to itself corresponds some substitution of its operators; and that to all such isomorphisms corresponds a substitution group, which has been called the *group of isomorphisms* of the given group. A new and simple proof was given of the following theorem of Jordan's: When a regular group (R) of order n is transformed into itself by the largest possible group (L) of its own degree, the subgroup of L which includes all its substitutions that do not contain a given element is the group of isomorphisms of R. Other theorems were proved regarding those isomorphisms which may be derived from a given one by means of real transforming operators.

In No. 2, of which a brief abstract was read by the Secretary, the general group is that of Lie's Kugelgeometrie. All infinity in space is regarded as a single point and all planes as spheres through the point at infinity. The general group is tenfold. All transformations leaving a point invariant form a sevenfold sub-group. There is a sixfold subgroup which leaves a sphere invariant, and which is identical with the sixfold group of circular transformations on the Neumann sphere or in the complex plane.

No. 3 was read in joint session of Sections A and B. It showed how to compute successive values of a function defined by a differential equation without solving the equation analytically. Using Newton's notation for derivatives of y as to x, and indicating successive values of y by subscripts, the simple trapezoidal rule would serve to express approximately the difference between $\dot{y}_0$ and $\dot{y}_1$ in terms of $\ddot{y}_0$ and $\ddot{y}_1$, and similarly that between y_0 and y_1 in terms of $\dot{y}_0$ and $\dot{y}_1$. Hence $\dot{y}_1$ and y_1 may be ultimately expressed in terms of y_0, $\dot{y}_0$, $\ddot{y}_0$, $\ddot{y}_1$. Substituting their values in the differential eqnation, the latter will give the value of $\ddot{y}_1$. This value substituted back will give values of $\dot{y}_1$ and y_1, and hence the quantities for the point 1 are completely

known when those for the zero point are assigned; and so on from point to point. The trapezoidal rule may be replaced by more accurate rules if desired. The method is applicable to equations of any order, and also to simultaneous equations.

No. 4 showed that if two matrices are commutative, *i. e.*, if $\varphi\psi = \psi\varphi$, then there is no latent system of any root of the one which lies in the extension composed of two or more latent regions of a root of the other unless it includes the entirety of these regions. The case when one of the matrices has equal roots was developed.

No. 5 presented a new theory of the quadratic equation $x^2 + 2bx + c = o$; stating that when b^2 is greater than c the roots may be either real numbers or 'hyperbolic complexes,' and that when b^2 is less than c the roots may be either 'circular complexes' or scalar numbers. In this view the square root of negative unity can in certain cases be interpreted as a scalar instead of a versor.

No. 6, which was read in joint session, showed by an example that when one term in the differential equation is the orthogonal projection of a plane motion, it is in some cases easier to pass to the auxiliary motion by means of 'planar algebra' than it is to proceed with the given equation directly. (See Trans. A. I. E. E., Vol. X., p. 186.)

In No. 7, of which the Secretary presented a brief abstract, there were $n - 1$ linear equations and one quadratic equation in the same n variables, and the problem was to determine when the simultaneous values of the variables that satisfy these equations are all real. The criterion obtained has applications for $n = 2, 3, 4$ or 5, whether the generating element be a point, a plane, a line or a sphere.

The object of No. 8, which was read by the Secretary, was to awaken an interest among astronomers and psychologists such as to induce them to pay more attention to the work of each other and thus improve their own methods where necessary.

In No. 9, which was presented in abstract by Dr. Shaw, the idea of obtaining the value of $A(m)$ the m^{th} compound of the determinant A, as a power of A by multiplying it by its adjugate $A(n - m)$, the $(n - m)^{\text{th}}$ compound of A, is extended to finding the value of certain minors of $A(m)$ in terms of A and its minors. By making use of a comprehensive notation the whole subject is unified, the laws of vanishing minors set forth, and such well-known theorems as Sylvester's and others are easily established.

In the absence of the author No. 10 was read by title, and a printed pamphlet was distributed in Sections A and B.

An abstract of No. 11 was presented by the Secretary. It stated that about 70 per cent. of the total magnetization of the earth can be referred to a homogeneous magnetization about a diameter inclined to the earth's rotation axis by an angular amount of about 12°. This axis has been termed by Gauss the earth's magnetic axis. It is an interesting question to determine the motion of this axis during the past two or three centuries, and Dr. Bauer's paper was an attempt to solve this problem as far as is possible with the data at present at command.

No. 12 was also read in brief abstract by the Secretary. It stated that as yet no formulæ had been found by which the diurnal range of the magnetic declination, for example, could be computed for various portions of the earth. The author has found the following simple formulæ to hold true within the fluctuations to which the quantities themselves are subject: Diurnal range of declination $= 2'.58 \sec^2 \varphi$; diurnal range of inclination $= 6'.1 \div 1 + 3 \sin^2 \varphi$; wherein φ, the magnetic latitude, is found from the equation $\tan \varphi = \frac{1}{2} \tan \mathrm{I}$, in which I is the magnetic dip. The first formula was discovered empirically, then under cer-

tain assumptions deduced theoretically. The second was then derived theoretically and was found to satisfy the data.

An abstract of No. 13 was read by the Secretary. It follows the theory of perturbations in the problems of mechanics in the order of its historical development from Lagrange to Lie with a view to the final presentation of the theory in its just position as one phase of Lie's theory of contact-transformations.

No. 14 was presented by the Secretary. It gave a bibliography of the Pythagorean proposition, followed by a general solution of the equation $x^2 + y^2 = z^2$, and concluded with an extensive numerical table of the sides of rational right-angled triangles.

No. 15 expressed in terms of the tabulated E and F functions a number of integrals, many of which had apparently never been completely worked out.

No. 16 showed how to express the effect of a small difference in the equatorial moments of inertia of the earth on the period of revolution of the instantaneous axis of rotation around the axis of figure. A remarkable value is obtained for the average angular velocity of that revolution, and a formula is deduced for the difference in the equatorial moments essential to explain the discrepancy between the observed and computed value of the Eulerian cycle.

No. 17 considered the case of no applied forces, or that in which there is conservation of moment of momentum. The problem is of practical interest in its application to the question of variation of latitudes on the earth. Several new theorems with respect to the motions of the mass were derived.

No. 18 obtained some general properties of a class of functions of which the spherical harmonics are special cases.

No. 19 described the present annoying state of the subject-matter of notation and coordinate systems, and advocated the adoption of certain standards. It is expected that this question will be further discussed at the Boston meeting with a view to obtaining a consensus on symbols and fundamental conventions.

No. 20 called attention to a certain quadrilateral whose properties throw new light on the theory of the Pascal lines of a hexagon inscribed in a conic.

In presenting No. 21 Professor Greenhill gave stereoscopic views of certain interesting curves in space and pointed out the bearing of some of them on certain parts of the theory of elliptic functions.

The section is also indebted to Professor Greenhill for interesting contributions to the discussions on many of the other papers.

The officers elected for the Boston meeting are Professors E. E. Barnard, of Yerkes Observatory, and Alexander Ziwet, of the University of Michigan.

JAMES MCMAHON.

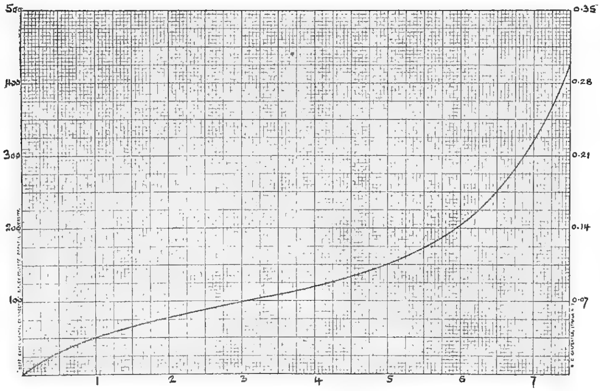
SINGULAR STRESS-STRAIN RELATIONS OF INDIA RUBBER.

THE curious and unaccountable behavior of India rubber in thermodynamic transformation of energy under load has long been familiar; it is, perhaps, even more generally known that it exhibits a peculiar relation of elongation to load when approaching its limit of tenacity, but I am not aware that this later phenomenon has ever been exhibited by formal test or by graphic representation of the results of such tests. It is a matter of common observation that, when this substance is subjected to a pull of steadily increasing intensity, its resistance increases as does that of any elastic and ductile material; but that, at the end, instead of suddenly losing power of resistance, or even snapping without observable decrease of load, its resistance for a time rapidly and largely increases up to the point

of rupture. This can be readily felt in even the breaking of one of the small bands of partially vulcanized rubber now so universally employed for filing papers and other purposes. At the end of the period of extension the resistance rises so rapidly as to produce the sensation of bringing the hand up against a rigid obstacle, resisting further elongation.

Figure 1 is the stress-strain diagram of a strip of rubber, partially vulcanized, but not sufficiently to disguise the peculiar characteristics of the material.

Studying this diagram, it will be observed that the substance behaves precisely like other familiar materials, up to a point which, in this case, is found at a load of thirty per cent. of the maximum, the breaking load, and at an extension one half the maximum. At this point there exists a reversal of the line, and the curvature is thence maintained convex to the axis of X, up to the point of rupture; fracture taking place, at the end, sharply and without any indication of that method of flow of the mass which, in the case of the irons and softer steels, for example, permits a falling-off of resistance after passing a point of maximum tenacity well within the breaking limit. The ratio of increase of load to increase of elongation steadily increases from the zero point, as with all substances, other than iron and steel, so far as known, up to this point of contrary flexure on the diagram; at which place the ratio is inverted and resistance increases in greater proportion than extension, finally assuming a comparatively high value.



Strain per Unit Length.

FIG. 1.—Stress-Strain Diagram of India Rubber.

The singularity of this action will be brought into relief by examining the diagrams produced with other materials employed in the arts.* Swedish or Norway Iron, Common Merchant Iron, 'Mild' Steel, and Tool-Steel have been subjected to loads increasing to the point of rupture, with occasional removal of the load.

*Thurston's Materials of Engineering, Vol. II., p. 611.

The nearly-vertical lines on each curve, at intervals, from the origin, are the 'elasticity lines,' as they have been called, showing the action of the material when the load is gradually relieved. These substances do not restore themselves to the original dimensions, but remain permanently distorted, taking more or less set and, usually at least, maintaining a constant value of the modulus of elascity. The slight droop in each line, near its outer extremity, shows the behavior of the substance when the load is left unchanged and elongation is maintained constant. This 'exaltation of the elastic limit' was discovered by me many years ago, and announced to the American Society of Civil Engineers in 1873.* India rubber exhibits none of the phenomena giving the characteristic form of the diagrams of the irons and steels. Even when stretched to the point of rupture it restores itself very nearly to its original dimensions and gradually recovers a part of the loss of form at that instant observable. Its almost complete stability of form when relieved from load, and especially when in the shape of springs such as are used on railway trucks, constitutes one of its most valuable properties. Like cork, when confined laterally, it is practically indestructible and incapable of distortion when used as a spring. The singular stress-strain relations of the substance may probably be found to give it peculiar value for many other purposes. The sample illustrated by our diagram was of the kind employed for springs and rubber bands and, as usual, slightly vulcanized.

The equation of the curve of this character described by the materials of construction generally may be taken, without important error, usually, as of the form

$$E=a\sqrt{T};$$

and with elongation, E, and T, tenacity, respectively, in per cent. of total length of specimen and in pounds per square-inch, the constant, a, is usually not far from 0.1 for good irons, 0.05 for tool-steels, and for good soft copper it is about 1.2. For this specimen of india rubber the equation is obviously so entirely different in class and form, and indicates so evidently an entirely different method of molecular action in resistance of strain, that it must constitute a problem by itself. The peculiarities of this form may, however, prove a key to the corresponding singularities of its internal structure and forces. So far as known, no other substance gives such unique relations of forces holding the substance in stable form to the variations of form to which the external application of force gives rise. The volume of the mass remains, so far as can be seen, constant, or nearly so, and the expenditure of work upon the substance results simply in changing the intermolecular distances of adjacent particles. This fact will probably be found to simplify the process of experimental interpretation of this curious case.

The cause of the singular behavior of this thermodynamically unique material remains to be discovered. It is probably safe to assume that its mechanical and physical properties will have some close relationship, and that the investigation, to be complete, must comprehend both lines of research. The gum must evidently possess either some very strange molecular force-relations or it must be the fact that, in the case of the ordinary materials of engineering and construction, these apparently peculiar characteristics are, in them, as yet unobserved because of their minute effects. The study of the subject cannot fail to lead to new and interesting facts relative to the molecular constitution of this and probably of other substances.

R. H. Thurston.

Cornell University.

FIFTEENTH ANNUAL REPORT OF THE COMMITTEE ON INDEXING CHEMICAL LITERATURE.*

THE Committee on Indexing Chemical Literature presents to the Chemical Section its fifteenth annual report, covering the twelve months ending August, 1897.

WORKS PUBLISHED.

Recalculation of the Atomic Weights. By FRANK WIGGLESWORTH CLARKE. New edition revised and enlarged. Constants of Nature, Part V. Smithsonian Miscellaneous Collections, 1075. City of Washington. 1897. Pp. vi+370. 8vo.

Index to the Literature of the Periodic Law. In: 'Development of the Periodic Law.' By F. P. VENABLE. Easton, Pa. 1896. 12mo.

Partial Bibliography of Argon. By C. LE ROY PARKER. Accompanying his paper: 'Our Present Knowledge of Argon.' J. Am. Chem. Soc. xix+124 (February, 1897).

Bibliography of Agricultural Chemistry (American). Bulletins of the Office of Experiment Stations, United States Department of Agriculture.

In our fourteenth annual report the following correction should be made: *for* Bulletin No. 9 *read* Bulletin No. 19, *and add* Bulletin No. 27 (1897).

A card-index to Experiment Station Literature is issued by the Office of Experiment Stations; this is sent *gratis* to all the agricultural colleges and experiment stations in the United States, and is sold to a limited number of individuals and institutions. Eleven thousand cards had been distributed prior to September, 1896.

The detailed index included in each volume of the 'Experiment Station Record' contains numerous references to chemical articles published by the experiment stations in the United States and in foreign countries.

Abstracts of Chemical Work in Agricultural Science, published in: 'Experiment Station Record,' issued by the Office of Experiment Stations, United States Department of Agriculture.

These abstracts were begun in Vol. I., No. 1. (September, 1889). Abstracts of foreign investigations were added, beginning with Vol. II., No. 8 (March, 1891), and these have been included, with a quite rapid growth in the field covered, up to the present time. The work is in charge of Dr. E. W. Allen, who is assisted by Mr. W. H. Beal in the department of fertilizers and soils, and by the Committee on Abstracting of the Association of Official Agricultural Chemists.

The Review of American Chemical Research, edited by Professor Arthur A. Noyes, begun in April, 1895, and formerly published in the 'Technology Quarterly,' is continued in the 'Journal of the American Chemical Society.'

Periodicals Relating to Chemistry and Physics in the New York Public Library and Columbia University Library. Bulletin of the New York Public Library, Astor, Lenox and Tilden Foundations. Vol. I. No. 6. June, 1897. Page 152.

A very convenient check-list compiled with bibliographical accuracy, especially useful to students residing in New York and vicinity.

Bibliography of the Analysis of Chrome-iron Ore, Ferro-Chromium and Chrome-steel. By S. RIDEAL and S. ROSENBLUM. *Chem. News,* Vol. 73, p. 2. (January 3, 1897.)

A Bibliography of the Chemistry of Chlorophyll, by L. Marchlewski, accompanies his monograph: 'Die Chemie des Chlorophylls.' Hamburg and Leipzig. 1895. 8vo.

REPORTS OF PROGRESS.

A Bibliography of the Metals of the Platinum Group, 1748–1896, by Professor James Lewis Howe, has been completed, and after examination by your Committee has been recommended to the Smithsonian Institution for publication. The work is now going through the press.

A Review and Bibliography of Metallic Carbides, by Mr. J. A. Mathews, of Columbia University, was submitted to your Committee, and after examination by each member the MS. was returned to the author for minor improvements. The suggestions of the Committee were promptly accepted by Mr. Mathews, and the revised work has been recommended to the Smithsonian Institution for publication.

A Bibliography of Basic Slags, Technical, Analytical and Agricultural, has been completed by Karl T. McElroy, of the Division of Chemistry, U. S. Department of Agriculture. The channel of publication has not been determined.

*Presented at the Detroit meeting of the American Association for the Advancement of Science.

The second edition of the *Catalogue of Scientific and Technical Periodicals*, 1665–1895, by Dr. H. Carrington Bolton, is entirely printed, but publication is deferred, owing to the preparation of a new Library Check List, with which it will be accompanied. The new edition contains 8,603 titles.

CHEMISTRY.

A Supplement to the Select Bibliography of Chemistry, 1492–1896, has been completed by Dr. H. Carrington Bolton, who has presented the MS. to the Smithsonian Institution. This Supplement contains about 9,000 titles, including many chemical dissertations, and is brought down to the end of the year 1896.

Dr. C. H. Jouet reports his *Index to the Literature of Thorium* 'nearly finished.'

Dr. F. W. Traphagen reports 'fair progress' on his *Index to the Literature of Tantalum.*

Mr. George Wagner reports that he has made progress on the *Bibliography of Oxygen.*

Mr. H. E. Brown, under the direction of Professor A. B. Prescott, is preparing a *Bibliography of the Constitution of Morphine and related Alkaloids.*

Professor William Ripley Nichols, of the Massachusetts Institute of Technology, at the time of his death left an unfinished *Index to the Literature of Carbonic Oxid;* the manuscript was taken in hand by Professor Augustus A. Gill, of the same institution, who has done considerable work upon it; he now reports that he is not in a position to finish the task and he is perfectly willing to relinquish the large amount of material accumulated to anyone who would undertake to complete it.

Professor Clement W. Andrews, formerly of the Massachusetts Institute of Technology and now Librarian of the John Crerar Library, Chicago, reports that he is obliged to abandon work on his *Index to the Literature of Milk*, and will be very glad to turn over the material to anyone who cares to undertake to complete the bibliography.

It has always been the aim of the Committee on Indexing Chemical Literature to prevent duplication of work, but failure to inform the Committee of work in progress may defeat this undertaking. An announcement, in the Fourteenth Annual Report, of certain work having been nearly completed surprised a chemist in another part of the country, and has led to the abandonment by the latter of much laborious indexing.

In conclusion the Committee repeats the statement that it labors to encourage individual enterprise in chemical bibliography, and to record in the annual reports works issued and works in progress.

Address correspondence to the Chairman, at Cosmos Club, Washington, D. C.

H. Carrington Bolton, *Chairman*,
F. W. Clarke,
A. R. Leeds,
A. B. Prescott,
Alfred Tuckerman,
H. W. Wiley,
Committee.

CURRENT NOTES ON ANTHROPOLOGY.

THE STONE AGE OF PHŒNICIA.

The associations of Phœnicia with both sacred and profane history are so numerous that a careful investigation of its oldest human remains will attract general attention. Such an investigation is reported in *L'Anthropologie*, Nos. 3 and 4 of this year, by Professor Zumoffen, of Beyrut, Syria.

He gives a map of the prehistoric stations, and divides them into 'paleolithic' and 'neolithic,' according to the French canons of archæology. Of the former he describes six which he has explored. Two full-page plates present the objects in natural size. The most important finds were in a cavern in the valley of Antelias, which has also been visited by previous students (Fraas, Dawson).

Examined by the canons of American archæology, the claim for the vast antiquity of these remains is open to some doubts. Patination, which the author emphasizes, is dependent on soil and dampness more than age; one or more of the six stations he acknowledges were workshops, and the remains, therefore, are to be classed as 'rejects.' This explains the absence of pottery; but most significant is the fact (p. 426) that the fauna of the 'paleolithic'

and the 'neolithic' stations were the same, while the stratigraphic relations of the deposits are inconclusive.

ARCHÆOLOGICAL SURVEY OF OHIO.

IN a neat pamphlet of 110 pages, reprinted from Vol. V. of the Ohio State Archæological and Historical Society, Mr. Warren K. Moorehead, Curator of the Society, gives a readable report of the field-work carried on in the Muskingum, Scioto and Ohio valleys during the year 1896. The exhibit is most creditable to his energy and judgment. The aim of his investigation is to produce a reliable archæological map of the State, and also to examine critically some of the most remarkable ancient monuments and to collect the art remains of the former inhabitants. In all these directions he has been quite successful. Nearly seven thousand monuments of the indigenous tribes have been located and mapped. A limited number have been carefully excavated, and the total number of specimens obtained runs up into the tens of thousands.

The report is illustrated with forty-five figures in the text of noteworthy mounds or valuable specimens, and much collateral information relating to them is inserted. One prominent advantage has been the educational influence of the survey on the population. It is gratifying to learn (p. 261) that there are now in Ohio 310 persons interested in its archæology! Can any other State equal this record?

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

NOTES ON INORGANIC CHEMISTRY.

PROFESSOR MOISSAN and Professor Dewar publish in the *Comptes Rendus* further experiments on liquid fluorin. The boiling point is −187°; at −210° it still remains liquid, showing no sign of solidification. The density was determined by suspending in it several different substances which are unacted upon; amber was found to rise and fall in the liquid, hence its specific gravity was 1.14. No absorption bands were found by the spectroscope, and between the poles of a powerful electromagnet it showed no magnetic phenomena. Its capillarity is less than that of liquid oxygen and only one-sixth of that of water. At −210° it has no action on dry oxygen, water or mercury, but at this low temperature it still reacts violently with hydrogen, and even with the hydrogen in oil of turpentine. The explosive substance which in previous experiments they obtained when fluorin was led into liquid oxygen is not formed if oxygen is perfectly dry, and appears to be a hydrate of fluorin.

IN the *Pharmaceutische Zeitung* F. Sibbers, writing on the analysis of aluminum, claims that the proportion of silicon present is always underestimated, from the fact that when aluminum is dissolved in acid a con-considerable part of the silicon is evolved as hydrogen silicid and lost. The average amount of silicon usually found in aluminum is 0.3 %, but taking into consideration that which is lost in analysis the author considers that 0.6 % is usually present. As the presence of silicon is considered to be very detrimental to aluminum, these determinations of Sibbers deserve careful consideration.

DR. H. CARRINGTON BOLTON, whose Bibliographies of Chemistry and Scientific Periodicals have proved of so much value to chemists and other scientists, as well as to librarians, and who has done so much to throw light upon obscure points in the history of chemistry, has again put American chemists under obligation to him by a paper on 'Early American Chemical Societies,' which was recently read before the Washington Chemical Society, and now is reprinted from the *Journal* of the American Chemical Society. It appears that before

the end of the first quarter of the present century three chemical societies had been founded in this country, while the first chemical society of Europe, the Chemical Society of London, was not founded till 1841. Forty-nine years before this date, in 1792, the Chemical Society of Philadelphia was instituted. Its first President was Dr. James Hutchinson, and at his death he was succeeded by Dr. James Woodhouse, who was at that time professor of chemistry in the medical department of the University of Pennsylvania. Among the best-known members were Dr. Joseph Priestley and Robert Hare, the inventor of the oxy-hydrogen blowpipe. "The meeting of October 24, 1801, was made memorable by the appointment of a committee for the 'discovery of means by which a greater concentration of heat might be obtained for chemical purposes.'" On this committee was Robert Hare, then only twenty years old, and December 10th of the same year he reported, on behalf of the committee, his great invention. No memoirs were published by this Society, and how much longer it existed is a matter of conjecture. In August, 1811, the Columbian Chemical Society was founded, also at Philadelphia. It numbered sixty-nine 'Honorary' (regular) members, of whom thirty-one were Europeans, and thirteen 'Junior' (associate) members. Thomas Jefferson was patron; James Cutbush, President, and among the more distinguished members were Benjamin Smith Barton, Archibald Bruce, Joseph Cloud, Thomas Cooper, Robert Hare, James Madison, Benjamin Rush, Adam Seybert and Benjamin Silliman. The foreign members included the most distinguished chemists of England and France, and Proust of Madrid. No Germans were on the list, nor Berzelius. One volume of memoirs was published in 1813, now a very rare book. In his article Dr. Bolton gives interesting abstracts of the papers in this volume. September 6, 1821, there was founded at Delhi, New York, the Delaware Chemical and Geological Society, a local society of forty or fifty members, having 'for its object the improvement of the members in literature and science, especially in chemistry and mineralogy.' Considering "the limited facilities for acquiring chemical knowledge in the New World" (chiefly in the medical schools) "and the distance of amateurs from the European head-centers of learning, it is certainly noteworthy that American chemists combined to form associations for mutual improvement and the advancement of their calling at so early a period." The fourth chemical society in this country was the American Chemical Society, founded at New York in 1876, and broadened in its scope in 1892, until it now numbers 1,106 members, working in nine chartered sections, representing forty-seven States and Territories, and several countries of Europe, South America, and even Australia.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

We record, with deep regret, the death at Philadelphia, on November 14th, of Dr. Harrison Allen, emeritus professor of comparative anatomy in the University of Pennsylvania.

The American Psychological Association will meet at Ithaca, in conjunction with 'The Naturalists' and affiliated societies, on Tuesday, December 29th, and the two following days, under the presidency of Professor J. Mark Baldwin, of Princeton University. It is intended to place papers on experimental and physiological psychology on the first day and on the final day papers having closer relations with philosophy. On Wednesday morning there will be a discussion on 'The Psychology of Invention,' which it is expected will be opened by Professor Josiah Royce, Harvard University; Professor John Dewey, University of Chicago, and Professor Joseph Jastrow, University of Wisconsin.

A committee of the American Chemical So-

ciety appointed in 1893 issued a circular letter addressed to foreign chemical societies, with a view to organizing a series of international chemical congresses, similar to the International Congress of Chemists held in connection with the World's Columbian Exposition. This committee has been compelled to report through its chairman, Professor F. W. Clarke, that a few favorable replies were received from minor organizations, but not from any of the great chemical societies, and the committee asks to be discharged, leaving the initiative to other organizations.

DR. B. ENGELHART has given up his observatory at Dresden and presented the instruments and library to the University Observatory at Kasan.

DR. MARK OLIVET, professor of psychiatry in the University of Geneva, and the author of numerous publications on medicine and hygiene, died at Geneva on October 24th, in his seventy-sixth year.

A MONUMENT to Duchenne has been erected in the Saltpêtrière. Duchenne began at Bologne by treating nervous diseases with electricity, and after he went to Paris never held any university or hospital position, but to him we owe the first description of locomotor ataxy and many forms of muscular wasting, as well as important advances in the physiology of movement.

PROFESSOR VON KÖLLICKER, Würzburg, has been given the Anders Retzius medal by the Association of Swedish Physicians.

PROFESSOR VON RÖNTGEN, Würzburg, has been elected an honorary member of the Swiss Scientific Society, Berne.

IT is stated in *Nature* that Professor F. Omori, of the Seismological Institute, Tokio, is now in India, for the purpose of investigating the recent Calcutta earthquake and reporting on the same to the Japanese government.

DR. LEHMAN NIETSCHE has been appointed keeper of the anthropological department of the La Plata Museum, succeeding Dr. Ten Kate.

THE Appalachian Mountain Club of Boston gave a reception on Monday of this week, at which were exhibited Harvard Geographical Relief Models, new Sella Photographs and photographs of the mountains along the Great Northern Railway. On November 10th Professor William M. Davis addressed the Club on the Harvard Geographical Models.

DR. KAKICHI MITSUKURI, the eminent zoologist, professor in the University of Tokio and delegate from Japan to the recent conference on seal fisheries, lectured this week at Johns Hopkins University, of which he is a former student.

THE following courses of lectures on natural science are being given at the Philadelphia Academy of Natural Sciences under the Ludwick foundation. They are given at 4:30 in the afternoon and admission is free. The subjects are: 'Malacology,' Professor Henry A. Pilsbry, November 1st, 8th, 15th, 22d, 29th, December 6th; 'Geology,' Professor Angelo Heilprin, November 2d, 9th, 16th, 23d, 30th, December 7th; 'Invertebrate Zoology,' Dr. Benjamin Sharp, November 3d, 10th, 17th, 24th, December 1st, 8th; 'Vertebrate Zoology,' Witmer Stone, M.A., November 5th, 12th, 19th, 26th, December 3d, 10th; 'Hygiene and Sanitation,' Dr. Seneca Egbert, January 7th, 14th, 21st, 28th, February 4th, 11th; 'Botany,' Mr. Stewardson Brown, January 10th, 17th, 24th, 31st, February 7th, 14th; 'Entomology,' Professor Henry Skinner, January 12th, 19th, 26th, February 2d, 9th, 16th.

AT the meeting of the Botanical Club of the University of Chicago, on November 9th, the hour was devoted to a brief review of the life of the late Professor Julius von Sachs. Professor Coulter read a translation of a short history of Sachs' life prepared by his pupil, Dr. Fritz Noll, which will appear in the *Botanical Gazette*. Professor Loeb then gave some personal reminiscences of von Sachs.

COMPLETE plans for the Zoological Gardens in Bronx Park have been prepared by Heins & La Farge, the architects, and were laid before the Park Commissioners on Monday. There has not been much change from the present topography of the Park, which the architects and experts found admirably adapted for the purposes of the Zoological Gardens.

AT the last meeting of the Trustees of the New York Public Library, Mr. Andrew A. Green offered a resolution for the appointment of a com-

mittee to consider and report on the expediency of uniting all the public libraries in the city. Mr. Green, Mr. Lewis C. Ledyard and General Philip Schuyler were appointed members of the committee. The intention of this resolution is to put all the public libraries under one working head and management and systematize the work throughout the city, the New York Free Circulating Library being the library that the the Trustees especially desire to have united with the New York Public Library.

The corner stone of the new building for the Bellevue Medical College, replacing that destroyed by fire and necessary owing to the failure of the plan for consolidation with New York University, was laid on the afternoon of November 13th. Mr. D. Ogden Mills, President of the Board of Trustees, made an address, and addresses were made in the Carnegie Laboratory by the Rev. Roderick Terry, of the Board of Trustees; Dr. Langdon Gray, representing the Alumni, and Dr. John S. Billings, for the medical profession. The new building, which occupies a plot of ground 75 x 100 feet, will be of granite and brick, five stories in height, and is expected to be ready in the spring.

At the inaugural meeting of the Röntgen Society, to which we referred last week, after the address by Professor Silvanus P. Thompson, there was an exhibition of apparatus and photographs. In its account the *Times* mentions only two exhibits, both from America: "In the hall a splendid assortment of photographs was exhibited, perhaps the most striking being a life-sized skiagram of the entire skeleton of a full-grown living woman, taken by Dr. W. J. Morton, of New York. Apparatus for the production of Röntgen rays was also on view, the chief novelty being an electric oscillator, made and specially sent by Mr. Tesla, in the construction of which no thin wire is employed. When one of Tesla's own tubes is excited with this machine the emission of Röntgen rays is so intense that, standing 50 feet away from it, one can still obtain on a luminescent screen the shadow of the bones of one's hands."

We learn from the *Botanical Gazette* that Dr. J. M. Rose returned from his Mexican trip early in October. His work was chiefly confined in the little-known parts of the Sierra Madre. He visited Guaymas, La Paz (L. C.), Mazatlan and Acaporeta, on the western side, crossed the two ranges of the Sierra Madre north of the Acaporeta and made two excursions into them, one from the west at Rosario, and the other from the east at Bolanos, the latter being one of Seeman's stations. The States chiefly explored were Durango, Jalisco, Zacatecas and the Territory of Tepic. The collection contained 2,000 numbers, and is especially rich in umbellifers, agaves and orchids, many living specimens of the two latter groups having been shipped for cultivation.

Mr. A. P. Morse, curator of the zoological museum of Wellesley College, has returned from a collecting expedition to the Pacific coast, planned under the direction of Mr. S. H. Scudder. He has brought back large collections, especially of orthoptera, for class work and for the museum.

A cablegram from Stockholm states that King Oscar and a number of private persons have contributed sufficient sums of money to insure the despatch of a Swedish Polar expedition in 1898, which will be led by Professor Nathorst, the geologist. The cost of the expedition is estimated at 70,000 crowns.

The seals caught at sea during the present season are said to be fewer than last year. The figures reported are as follows: Total catch of seals in the north Pacific for the present season, 38,700 against 73,000 last year. The catch in Bering Sea, which is that portion of the north Pacific in which the United States is interested, is 16,650 for the present season, against 29,500 last season, a reduction of about one-half. Of the catch in Bering Sea, British vessels took 15,600, American vessels 1,050.

Mr. H. C. Mercer and Professor H. C. Warren have retired from the board of associate editors of the *American Naturalist*. We understand that hereafter anthropology and psychology will not be included in the scope of the journal.

The *Asa Gray Bulletin*, edited by Mr. J. H. Hicks, is now being published at Washington as a bi-monthly magazine for popular botany.

Beginning with next year, a journal, enti-

tled *Archives de Parasitologie*, edited by Professor Raphael Blanchard, will be published at Paris.

THE current number of Virchow's *Archiv* is the 150th and is published fifty years after the establishment of the *Archiv*, in 1847. It contains a portrait of Virchow and two articles added to the long series contributed by him since he published seven in the first volume, fifty years ago.

THE *Open Court* for the present month has as a frontispiece a portrait of Euler and publishes some biographical notes on the great mathematician. Portraits of other mathematicians will be given in other numbers of the journal.

MESSRS. HOUGHTON, MIFFLIN & CO. have published for the Appalachian Mountain Club, of Boston, a guide book to the region about the city, prepared by Mr. Edwin M. Bacon. It contains 410 pages, with four folding maps and 150 illustrations. The opening chapter quotes President Eliot's characterization of the country round about Boston as the most interesting historical region in the United States, and one of the most beautiful he had ever seen here or in Europe; and his advice to the students is 'to learn the whole region by heart.' For this purpose the book, which pays special attention to the natural history of the region, will be a most useful guide.

IN a recent paper, published in the Transactions of the Edinburgh Field Naturalists' and Microscopical Society, Mr. Symington Grieve brings the history of the Great Auk down to July 31st of this year, noting the new specimens of eggs which have come to light within the past few years as well as the changes that have taken place in the ownership of specimens. It appears that the highest price paid for an egg was 300 guineas by Sir Vauncey H. Crewe, while Mr. Rowland Ward gave 600 guineas for a skin and egg. The article is accompanied by five plates of mounted specimens, three of which are of special interest from the fact that they are from young individuals.

ACCORDING to the *Botanical Gazette* the two important collections left by the late Dr. Edmund Russow, of the University of Dorpat, are to be sold. One is a collection of about 3,750 fully prepared and well preserved microscopical preparations, including the original mounts used for the late owner's classical investigations. The second collection is the Sphagnum collection, of which group Russow was known as one of the foremost students. It consists of 314 fascicles and about 3,000–4,000 microscopical preparations, with outline sketches of the same, especially of the species that have been already worked up. There are, in addition, 300 photographic lantern slides of localities of the different sphagnums. Further information regarding the collections may be obtained from Frau Professor Emma Russow, Schloss Str., 15, Dorpat, Russia.

REUTER'S agency reports that at the headquarters of the Russian Imperial Geographical Society, on the 27th inst., M. Sven Hedin, the celebrated Swedish traveler, delivered an address before a large and brilliant audience upon his recent journey across the Pamirs, Kashgaria and the Lob Nor. He started at the beginning of 1894 for the Pamir military post in Kashgaria, and ascended and mapped the glaciers of Mustagh Ata (20,000 feet). During the autumn he proceeded in the direction of Lake Teschil-Kul to explore it, and also the Alid-Schur Mountain range. He returned to Kashgar to pass the winter, and spent the time in arranging the scientific material which he had collected. In February, 1895, M. Sven Hedin set out to cross the Takla Makhan desert, but was compelled to return to Kashgar. In December, 1895, he went by way of Khotan towards Lake Lob Nor, traversing a desert 300 km. wide. During this journey which occupied four months and a half, M. Sven Hedin discovered the remains of two ancient towns and the ruins of Buddhist monuments. Proceeding as far as the Kiria Daria river he ascertained that this stream ran as far as 39° 30′ N. He found in that region a tribe of half-savage shepherds, unknown even to the Chinese. Pushing on to the Chinese town of Koreia, along the banks of the river Tarim, M. Sven Hedin reached the Chinese, or northern, part of Lake Lob Nor. From LobNor, in the spring of 1896, he came back to Kholan, and then returned to Kipa, in order to undertake a journey in north-

ern Tibet and on the heights in that region. During this expedition the explorer discovered a lofty mountain range, whose highest peak rose about 24,000 feet above sea level. This was named Mount Oscar. He also found in this region twenty-three salt-water lakes. M. Sven Hedin then proceeded *via* Tsaidam, Kuku Nor, Si-ning-fu, Liang-chu, the deserts of Alashan and Ordos to Peking, which city he reached on March 14, 1897, across northern China. The expedition, the cost of which was defrayed by the King of Sweden, M. Nobel and several other rich Swedish gentlemen, was the means of securing botanical, geological and archæological collections, notably several ancient Buddhist MSS., found at Khotan, and about 500 sheets of topographical plans, as well as a large number of photographs.

THE lecture at the annual public meeting of the five Paris Academies was given by M. Moissan, who chose as his subject 'The University of Chicago,' and made use of impressions obtained on his recent visit to America. The address, published in the last number of the *Revue Scientifique*, may be read with profit and amusement. After an introductory paragraph M. Moissan begins: "Il y avait une fois, à l'Université de Yale, près New-Haven, un professeur de langues hébraïques nommé Harper. Cet homme, qui avait beaucoup voyagé et qui connaissait bien les établissements d'instruction de son pays, avait la prétention de fonder la plus grande université des Etats-Unis. Sans cesse il poursuivait cette pensée, s'enfermant en elle et lui donnant le meilleur de son intelligence. Son idée devint une idée fixe, et ce qu'il y avait de plus grave, c'est qu'il raisonnait parfaitement son cas. Il prétendait, ce professeur d'hébreu, qu'une université vraiment digne de ce nom devait présenter certaines qualités particulières. Il voulait, par exemple, la séparation complète de l'enseignement supérieur et de l'enseignement secondaire, ce qui ne se fait pas souvent aux Etats-Unis."

THIS year's experience with yellow fever in the South, which has cost the country more than sixty million dollars, says the Boston *Transcript*, has led to a movement among medical and scientific men to have the disease studied more thoroughly than heretofore and, if it is possible, to control it as they have other infectious and contagious diseases. A committee of seven, which was appointed by the American Public Health Association at the annual meeting in Philadelphia a short time ago, has waited upon President McKinley and laid before him the urgent necessity, as viewed by the Association, for the appointment by Congress of a commission of expert bacteriologists to be sent to Havana for the purpose of making a thorough study of the cause and prevention of yellow fever. This committee consists of Dr. H. B. Horlbeck, Charleston, S. C.; Dr. Samuel H. Durgin, of Boston; Dr. A. H. Doty, of New York; Dr. G. M. Sternberg, U. S. A.; Josiah Hartzwell, Canton, O:; Dr. S. R. Olliphant, New Orleans, La., and Dr. R. M. Swearingen, Austin, Tex.

THE last number of the *Journal of Comparative Neurology* contains the text of four 'Lectures on the Sympathetic Nervous System,' given before the medical students of the University of Michigan in May, 1897, by Dr. G. C. Huber. The newer literature is critically reviewed in the light of the author's own researches, which are also quite fully outlined, and especial attention is devoted to the problem of the relation of the neurons in the sympathetic system. The original figures illustrate the sympathetic endings on striated and non-striated muscle cells, cardiac muscular cells, blood vessels, gland cells, epithelium of the bladder and the cells and pericellular baskets of the sympathetic ganglia of various vertebrates, together with diagrams in colors of the course and distribution of several systems of sympathetic neurons.

THE report of the Engineer-in-Chief of the United States Navy, just issued, includes the statement of the year's work in testing materials for machinery by Chief Engineer E. R. Freeman, who has had charge since the late change of policy, which permitted the assignment of work to engineer officers which had previously often been largely performed by inexpert officers of other departments. The supervising inspector reports that the present system of conducting the inspection of steel has thus

far proved very satisfactory, and has a very decided advantage over the former system in the point of time required to establish understandings between the manufacturers and the Bureau. There are many questions arising in the inspection of steel which can be decided or answered only by reference to the Bureau's plans and specifications, and which now come direct to the Bureau; whereas under the former system of inspection they came through the Steel Inspection Board, and the information desired in connection with them was, of course, returned to that Board for its decision, thus causing much delay. The inspection of steel and the designing of machinery made of that material being now under one head, the plans and specifications for that machinery and the specifications for that steel can be better adapted to the full capabilities of the steel maker, and will not be apt to ask of him anything beyond his capabilites.

THE visitation of Algeria by locusts last year is described in the last report of the British Consul-General, which is quoted in the London *Times*. It seems that Algeria was visited twice during the year, the first flight appearing in the winter as far north as the Mediterranean coast, and a second one, which was normal, in the spring and early summer. There is no record of any flight such as the early one in the history of Algeria, and as they appeared so early it was believed they were sterile; but the females began to lay in the usual way, only several months too soon. But in place of being hatched out in the usual period, they took more than twice as long, which seems to be something wholly new and unexpected in the life history of locusts. The appearance of the insect so far north as the Mediterranean in mid-winter is believed to be due to the drought which in the previous year devastated the southern districts and the Morocco Sahara. There being no vegetation in the Sahara, the locusts were forced to leave the grounds where they spend the winter, and, without making the usual halts, to hurry forward to places where food was obtainable. Up to this it was believed that the *maximum* period for the incubation of the eggs was 45 days; but it has been shown now that it extends in some cases to 70 days, so that the period may vary, according to the time of the year, from 15 days to 70. This unexpected visitation was met by exceptional exertions on the part of the government, the local authorities and trade committees. Oran, the province adjoining Morocco, was the only one invaded. The area over which the eggs were laid is estimated at 424,500 acres, and 270,120 bushels of young locusts were destroyed. The barriers, or lines of defence, made of the Cyprus apparatus, or of zinc, extended over 322 miles, while 27,113 ditches were dug at the foot of these to catch the young locusts. These figures do not take into account the work done by the administration of forests. The number of days' work furnished by natives during the campaign was 90,033. The efforts of the defenders were devoted mainly to saving the crops which were most valuable, such as the vines, and are said to have been very successful.

THE London County Council has adopted the following resolution: "That it be referred to the Parks Committee and to the Technical Education Board to consider and report as to the practicability of laying out plots of ground in certain parks in such manner as will afford assistance to scholars of elementary and secondary schools in the study of practical botany."

UNIVERSITY AND EDUCATIONAL NEWS.

THE report of the Treasurer of Yale University states that the additions to the funds of the institution during the past year amounted to $450,055, largely from the Fayerweather legacy. During the past ten years the funds of the University have been about doubled.

THIRTY scholarships have been established in the department of philosophy in the University of Pennsylvania, ten of which will be available this year, twenty next, and the whole number the following year.

PLANS have been adopted for the new Wilder physical laboratory at Dartmouth College. The building will be of brick, three stories high, 107 feet long by 56 deep, with a wing in the rear. It will front on College street, between the Richardson Hall and the Medical College. The building will provide lecture rooms and

laboratories for chemistry, physics and astronomy.

A movement has been started at Raleigh, N. C., for the establishment by the State of a textile school. A committee has been appointed to correspond with all mill-owners, newspapers and Legislators. In the Georgia Legislature a bill is pending for the appropriation of $10,000 for the establishment of a textile school.

On the recommendation of the governing board of the Sheffield Scientific School of Yale University, it has been decided to establish the degree of Master of Science, to be conferred on graduates of two years' standing or upwards, who have taken a first degree in science and who pursue successfully a higher course of study in science under the direction of the governing board.

Dr Lafayette B. Mendel has been promoted to an assistant professorship of physiological chemistry in Yale University.

Dr. George T. Kemp has been appointed professor of physiology in the University of Illinois.

The director o Sibley College, Cornell University, has been authorized to establish a full professorship of railway machine design and locomotive construction. At present this work is carried on in existing departments.

Professor Oscar Loew, who has been for four years professor of agricultural chemistry in the University of Tokio, has returned to Munich. He will be succeeded by Dr. Bieler, now assistant in the laboratory of agricultural chemistry at Halle.

A croom Robertson fellowship with an endowment of £8,000 has been created in the University of Aberdeen, with which Robertson was connected before being called to the Grote chair of philosophy of mind and logic in University College, London.

A chair of geography has been established in the University of Würzburg.

The Technical Institute in Munich has been given by the government 175,000 Marks for enlarging the electro-technical laboratory, 150,000 Marks for the erection of a laboratory for the agricultural station and 170,000 Marks for enlarging other buildings.

The newly established medical school for women in St. Petersburg opens with 165 students.

The Russian government has appropriated 400,000 roubles for the construction of a chemical laboratory at the Polytechnic Institute at Riga.

DISCUSSION AND CORRESPONDENCE.

DETERMINATE VARIATION AND ORGANIC SELECTION.

A few remarks may be allowed on the subject discussed in the reports of the papers of Professors Osborn and Poulton, on 'Organic Selection' in the issue of October 15th. I venture to make these comments now, although the more extended publication of the articles of the authors may remove my *causas scribendi.* Yet such preliminary reports have their main utility, to my mind, in arousing comments which may be of service to the authors.

I may throw my remarks into heads for the sake of clearness.

1. Professor Osborn's use of the phrase 'determinate variation' I find ambiguous, and the ambiguity is the more serious since it seems to me to prejudice the main contention involved in the advocacy of 'Organic Selection.' The ambiguity is this: He seems to use *determinate variation* as synonymous with *determinate evolution.* (See his discussion, Science, Oct. 15, pp. 583–4, especially p. 584, column 1, and paragraph 2 of column 2.) He says that *determinate variation* is generally accepted, and attributes that view to Professor Lloyd Morgan and myself. But it is only *determinate evolution* that I, for my part, am able to subscribe to; and I think the same is true of Professor Morgan.

'Determinate evolution' means a consistent and uniform direction of progress in evolution, *however that progress may be secured, and whatever the causes and processes at work.* Admitting 'determinate evolution,' the question, therefore, as to the causes which 'determine' the evolution is still open, and various answers have been given to it. The Neo-Lamarckians say

'use-inheritance' (as Eimer, who calls the determination secured by this means *Orthogenesis*); Weismann says, 'germinal selection; I have suggested 'Organic Selection' (the resulting determination of evolution being called by me 'Orthoplasy'); others say, 'determinate variation' (continued in the same direction for successive generations); Professor Osborn says, 'determinate variation' with 'organic selection.' *Determinate variation*, then, in the proper meaning of that term, is only *one way of accounting for determinate evolution;* and to my mind, it is not the true way; at any rate it is not at all involved in the theory of 'organic selection' as I have advocated it.

Let us look more closely at 'determinate variation.' Supposing that by variation we mean 'congenital variation,' then we may ask: When are variations determinate? When for any reason they are distributed about a mean different from that required by the law of probability or chance. The problem of determinate variations is purely one of *distribution*; and is to be investigated for each generation, quite apart from its holding for a number of successive generations (and so giving 'determinate evolution').

Further, the possible determinateness of variation is to be distinguished carefully from the *extent* or *width* of variation. By 'extent' of variation is meant the limits of distribution of cases about their own mean; while relative determinateness means the distribution of cases about a mean established in the earlier generation. The question of determinate variation is: *Has any influence worked to make the mean of variation of the new generation different from that which should be expected from the characters of their parents,* * *whatever the extent of variation.*

*I expressly avoid saying what this mean is, *i. e.*, what the contribution of each parent is to the average individual of their offspring; but the work of Galton goes far to establish it. Much more investigation is needed on this point of making out what is indeterminate variation; how insecure, therefore, the claim that variations are determinate! The drift of recent statistical studies goes, however (as far as I am familiar with them), directly to show that in their distribution—considered apart from their extent— variations follow the probability curve.

2. As I have said in a recent article * the assumption of the paleontologists (Osborn, *loc. cit.*, pp. 584–5) that because certain fossils show determinate progress—*determinate evolution*, therefore there must have been *determinate variation*, seems to me defective logic. It is one possibility among others, certainly, but only one. And as I held in the same article, instead of being necessary as a support for organic selection, the latter comes as a new resource to diminish the probability that the variations have really been determinate in these cases. They may be cases of orthoplasy involving organic selection working as an aid to natural selection upon 'coincident' variations which are yet not determinate but fortuitous in the strict sense.

3. Without going into the question, I may yet point out that the position taken by Professer Poulton in the matter of the relation of natural to organic selection is, as he says, that advocated by me (with some of the same arguments); but it may be recalled that I gave natural selection still further emphasis by making the 'functional selection from overproduced movements,' whereby motor accommodations are secured, itself a case of natural selection broadly understood. I have recently drawn up a table showing the various sorts of 'selection' under the distinction of 'means' and (immediate) 'result,' finding some twelve sorts of selection. I venture to reprint this table here, with the remarks which accompany it in my book on 'Social and Ethical Interpretations in Mental Development' (Macmillan, 1897), hoping that it may be discussed. The terms in the table which relate to social evolution are fully explained in the book; they are not so essential to the topic now before us.

The table and the remarks upon it (*loc. cit.*, Appendix B), slightly revised, are as follows:

"The various sorts of 'Selection' which it seems well to distinguish in different connections may be thrown together in the following table, the corresponding sections of the book (as far as there are such sections) being in each case given in brackets in the table beside the description:

* *The Psychological Review*, July, 1897, p. 397.

SELECTION.*

SORT.	MEANS.	RESULT.
1, 2. Natural Selection { I. Darwin, Wallace, Spencer) [40]. II. (Eimer) [40].	1. Struggle for Existence (Darwin, Wallace). 2. Inherent Weakness, without Struggle.	1. 'Survival of the Fittest' Individuals (Spencer). 2. Destruction of Unfit Individuals.
3. Germinal Selection (Weismann).	3. Struggle of Germinal Elements.	3. Survival of Fittest Germinal Elements.
4. Intra-Selection (Roux, Weismann, Delage).	4. Struggle of Parts (Roux).	4. Survival of Fittest Organs.
5. Functional Selection (Baldwin).	5. Overproduction of Movements (Bain, Spencer, Baldwin).	5. Survival of Fittest Functions.
6. Organic Selection (Baldwin, Osborn, Lloyd Morgan) [Appendix A].	6. Accommodation (Baldwin); Individual Adaptation (Osborn); Modification (Lloyd Morgan).	6. Survival of Accommodating Individuals.
7. Artificial Selection (Darwin).	7. Choice for Planting and for Mating together.	7. Reproduction of Desirable Individuals.
8. Personal Selection† [40].	8. Choice.	8. Employment and Survival of Socially Available Individuals.
9. Sexual Selection (Darwin) [40].	9. Conscious Selection by Courting, etc.	9. Reproduction of Attractive Individuals.
10. Social Selection† [40, 120].	10. Social Competition of Individuals and Groups with Natural Selection (Malthus, Darwin).	10. Survival of Socially Fittest Individuals and Groups.
11. Social Suppression† [38 ff].	11. Suppression of Socially Unfittest (by Law, Custom, etc.).	11. Survival of Socially Fit.
12. { Imitative Selection† [40, 121, 307]. Social Generalization† [121, 310 ff]	12. Imitative Propagation from mind to mind with Social Heredity.	12. Survival of Ideas in Society.

"Certain remarks may be added, to which I give numbers corresponding to those topics in the table to which they respectively relate:

"4, 5, 6. By a singular coincidence M. Delage uses the phrase 'Selection organique' (*Struct. du Protoplasma*, etc., p. 732)to describe Roux's 'Struggle of the Parts.' Seeing that Weismann's 'Intra-Selection (4) was directly applied by him to his interpretation of Roux's 'Struggle,' Delage's phrase is not likely to have currency as a substitute for Intra-Selection. As 'Functional Selection' (5) is a special means of motor accommodation, it is additional, and in a sense subordinate, to Intra-Selection, since it has a *functional* reference.

"7, 8, 9. I do not give a separate heading to Professor Lloyd Morgan's phrase 'Conscious Selection,' since it will be seen that, as he uses it, *i. e.*, in broad antithesis to 'Natural Selection,' it really includes all those special forms of selection in which *a state of consciousness plays the selecting role** (7, 8, 9, 11, 12); it may become ambiguous in reference to cases where *natural selection operates on mental and social variations* (5, 6, 10); and even when applicable, as in 'Sexual Selection' (9),† with respect to the 'means' of the selection, it is still ambiguous with respect to the 'results' of the selection. This last ambiguity, which is brought out in the table (8, 9),‡ makes it desirable to confine the phrase 'Conscious Selection' (if used at all) to cases which result in continuance of what is de-

*I am indebted to Professor Lloyd Morgan for several suggestions utilized in the Table.

† Suggested in this work.

*This, indeed, is still liable to the question as to *whose is the state of consciousness*, giving the difference (both in means and result) seen between 'Artificial' (7) and 'Sexual' (9) selection. It is strange that Professor Morgan makes no allusion (?) to Romanes' earlier suggested term 'Psychological Selection.'

† Lloyd Morgan, *Habit and Instinct*, pp. 219, 271.

‡ The bird 'selects' (sexually) for the sake of the experience, and it is a secondary result that she is also thus 'selected' for mating with the male and so for continuing his attractive characters with her own characters in the offspring.

sirable for consciousness or thought. I have suggested 'Personal Selection (8) for the selection *of* individual persons *by* personal choice, analogous to 'Sexual Selection' (9) in the animal world. Furthermore, Darwin's 'Artificial Selection' should be used, as he used it, with reference only to securing results by induced mating.

"10, 11, 12. In all sorts of so-called 'selection,' *considered as factors in progress from generation to generation, in which the laws of natural selection and physical reproduction do not operate together*, I think it is extremely desirable that we discard the word 'selection' *in toto*, and give to each case a name which shall apply to it alone. The cases of the preservation of individuals and groups by reason of their social endowments do illustrate natural selection with physical reproduction, so I propose 'Social Selection' (10) for that. But in the instances in which either physical heredity is not operative (12), or in which it is not the only means of transmission (11), we cannot secure clearness without new terms; for these two cases I have suggested 'Social Suppression' (11), and 'Social Generalization' (12). The phrase 'Imitative Selection' is given in the table alternately for the latter (12), seeing that the discussions of the topic usually employ the term 'Selection' and use (wrongly) the 'Natural Selection' analogy. Selection may be used also when there is no reference to race-progress (and so no danger of the misuse of the biological analogy); since it then means presumably the 'conscious choice' of psychology and of pre-Darwinian theory."* J. MARK BALDWIN.

PRINCETON, October 20, 1897.

* It may be well to add that this table is not intended to be altogether exhaustive from the biological standpoint. For example, Professor Minot's 'Post-Selection' and Romanes' 'Physiological Selection' do not fall readily into the scheme. Nor are the different headings in all cases exclusive of one another, *e.g.*, Darwin really included both the cases (I. and II.) of Natural Selection under the single phrase; and justly so, seeing that they illustrate a single principle.

AMPHIBIA VS. BATRACHIA.

I HAVE been much interested in reading the communications of Dr. Gill and Dr. Baur on the above subject, and having developed certain convictions thereon I beg leave to state them. Before proceeding to do this I wish to express my appreciation of the reasonableness of the condition of doubt in which Dr. Wilder finds himself.

Formerly I employed the term *Batrachia*. Later I became inclined to regard *Amphibia* as having superior claims, principally because it has been used and insisted on by many careful writers. I trust that my present views rest upon a better foundation.

In Dr. Baur's communication of July 20th his conclusion is summed up in the following words:

"Three years later Latreille used the Latin names *Reptilia* and *Amphibia* for de Blainville's classes *Reptiles* and *Amphibiens*, and these names ought to be used."

However, it appears to me that he has failed to tell us why they ought to be used; that is, he has not stated the principles which make it obligatory on us to use them. He has only given us an excellent history of the case and his conclusion. We have definite laws governing the formation and use of generic and specific names, but the only law cited by Dr. Baur which applies to appellatives of higher rank is that which deprives of binding authority all vernacular names, even though they may seem to imply the Latin forms. This rule, which most naturalists will endorse, materially clears the ground in the present case. Chéloniens, Ophidiens, Batraciens, and Amphibiens stand on the same footing as Schildkröten, Schlangen, Toads, and Turtles.

It might be supposed that Dr. Baur relies on the law of priority to sustain him, since he is so careful, and properly so, to give the dates of proposal of each of the names employed; but the fact that he rejects *Ranæ* as a name for the frogs, etc., makes it evident that he demands something more. Dr. Gill says that we must be guided by the law of priority in the selection of names.

One thing is very certain, and that is that we cannot rigidly enforce, with respect to the appellatives of higher rank, the same rules that apply to genera. Common usage must and does determine much in the case of the former terms. The law of priority and a desire to

preserve Linnæus' names would probably impel us to overthrow the usurping title *Elasmobranchii* in favor of Linnæus' quite appropriate word *Nantes*. Linnæus' apt *Testacea* has been crowded out of all authority by the upstart *Mollusca*, which, originally ruling over a petty section of heterogeneous elements, now stands at the head of a vast sub-kingdom. Linnæus' beautiful name *Zoophytes* is now replaced by *Cœlenterata*, suggestive of famine. The strict law of priority applied to the term *Reptilia* would result in restricting it to ordinal rank or in worse consequences. Laurenti, 1768, employed it to include Linnæus' *Amphibia* minus the *Nantes*. It then either became a synonym of *Amphibia* or restricted the latter term to the *Nantes*. But the man who at this day attempts to oust *Reptilia* from its position in nomenclature will shed his ink in vain. Furthermore, the contest for the headship of the class embracing the frogs and salamanders lies between *Amphibia* and *Batrachia*. No *Ranæ*, *Ichthyoidea* or *Nudipellifera* need apply.

A word now regarding the use of the word *Amphibia*. Linnæus and some of his disciples included under it not only the reptiles and batrachians, but also various fishes. These being at length excluded, the term was employed for nearly a hundred years by various writers of standing to embrace all the reptiles and ranine and salamandrine forms. In 1825 it seems to have been used for the first time by Latreille, to designate what are now commonly called the batrachians, or amphibians. This is the date given by Dr. Baur, and is most probably the correct one.

In 1804 Latreille recognized the fact that the frogs and salamanders form a natural group, and he called this group the order *Batrachii*. We can hardly suppose that this name will be rejected because of its masculine ending. But if so, the honor of giving the name to the group belongs to Gravenhorst, who in 1807 called it *Batrachia*. But the advocates of *Amphibia* reject Gravenhorst's name, because it was used for the group as an order. Then, must every group be rechristened whenever its rank is changed? I know of no rule of nomenclature requiring this, nor does common usage demand it. Most ichthyologists regard the *Elasmobranchii* as a subclass of *Pisces*. Must those who consider it a distinct class seek a new name? Whenever the word *Mollusca* was applied to the group of mollusks the name dated from that time, even though the group may still have been looked upon as an order of *Vermes*. In the words of Professor Cope (Batrachians N. A., p. 20), 'the rank assigned to such division is immaterial; the idea of the division itself is everything.'

But even in case it were necessary to estimate correctly the value of a group when its name is applied to it, the term *Batrachia* may yet succeed in running the gauntlet. In 1820 Merrem recognized in Linnæus' *Amphibia*, minus the *Nantes*, *two distinct classes*. These he named and adequately defined. The one, *Pholidota*, corresponds to our *Reptilia;* the other he called the *Batrachia*, and it corresponds with the group now so-called. What rule or practice of nomenclature was not complied with by Merrem in this case? This was five years before Latreille restricted the title *Amphibia* to the same class.

If I correctly understand Dr. Baur, he rejects Merrem's name because the latter writer still considered his classes as holding such a relation to each other that they might be brought under the name *Amphibia*, regarded, perhaps, somewhat in the sense of a super-class. Is there any law against this? Such a law would have to be formulated somewhat thus: A class name to be acceptable must originally have been applied to the group regarded as a class, and the author must have entertained opinions now held as orthodox regarding the relationships of his class to other classes.

In conclusion, I will say that, from the evidence now in, it appears to be a very plain case in favor of the defendant, *Batrachia*. I should say that it dates, as a name, from Latrielle, 1804, or from Gravenhorst, 1807; most certainly not later than Merrem, 1820. *Amphibia* has been employed in so many senses that it leads to confusion. It should be reserved for those who may now or hereafter hold there is some special relation between the reptiles and batrachians.

I am sorry to differ with my friends, Dr. Gill and Dr. Baur.

O. P. Hay.

U. S. National Museum, September 24, 1897.

THE BRITISH AND AMERICAN ASSOCIATIONS.

TO THE EDITOR OF SCIENCE: Those members of the American Association for the Advancement of Science who went from Detroit to Toronto naturally made comparisons as to the methods by which the affairs of the two organizations were conducted. Permit me, therefore, as one who attended both meetings, to suggest three things which, if properly carried out, will tend to improve, at least to a certain extent, some features in the American Association.

First. The addresses of the President and Vice-Presidents of sections should be in type and ready for publication at the time of the meeting of the Association. By this means the addresses would be available to the daily and scientific press, and every address would be given out at the same time. At Detroit the President's address was not properly reported by any local newspaper, and of the Vice-Presidential addresses only that of Professor Mason was available in pamphlet form.

Second. All papers passed by the sectional committee should go through the hands of a competent press secretary, specially hired for the purpose, preferably a scientific man, who should prepare suitable abstracts of the same for publication. These abstracts should be duplicated by some convenient copying process and given to reporters as desired.

By the combination of these two methods a proper and dignified presentation of the work of the Association would be given to the public, and by using the same for the proceedings the publication of the volume could be begun at once at the close of the meeting. For with the addresses in type and the abstracts in manuscript the volume could be put together and issued as soon as it could be printed.

Third. In lieu of the single public reception given on the first evening of the meeting I would advocate a greater number of social functions at which the members could meet each other. At each meeting of the British Association, besides a reception, there is always a conversazione and a subscription dinner which is given in honor of the retiring President. Would not such gatherings tend to bring the members of our Association into closer relationship with each other? For, after all, it is often the spoken word rather than the formal paper that suggests a line of research or is most fruitful in aiding workers in science.

MARCUS BENJAMIN.

U. S. NATIONAL MUSEUM, November 6, 1897.

SCIENTIFIC LITERATURE.

Boletin del Instituto Geologico de Mexico. Nums. 7, 8 y 9. El Mineral de Pachuca.

Since the Geological Survey of Mexico was placed in charge of Sr. J. G. Aquilera, two or three years ago, the work has been prosecuted with great energy and several quarto bulletins, well illustrated, have been issued. These include a sketch of Mexican geology, studies of rocks and fossils as well as studies of special areas.

The volume named at the head of this note gives the results of detailed examination of a well-known region which, more than once, has attracted the attention of European geologists. There are chapters by nearly all members of the staff, illustrated with 8 large maps and diagrams and 6 quarto plates. These describe elaborately the physiography, general geology, veins, and microscopic character of the rocks as well as matters of economic interest.

The district of Pachuca, not far from Mexico, is almost midway in the Sierra de Real del Monte y Pachuca, on the lower half of the westerly slope and near the southwest border of the Sierra. It embraces about 20 square kilometers and its principal mines are in three ravines which unite to form the Rio de Pachuca. Its output of silver in former years was almost fabulous, but since 1895 it has been practically idle, owing to the flooding of the mines. Now, however, the drainage operations promise to be successful and the geological structure of the region becomes of much interest to Mexicans.

The rocks are all eruptives, though sedimentary deposits, most probably Cretaceous, are shown within a short distance. Andesites, rhyolites and basalts are the forms, and of each there occur numerous varieties in texture, color and composition. The chapter on the general geology by Aguilera and Ordoñez gives much detail respecting the macroscopic features of these rocks and their chronological relations. The authors feel justified in concluding that

there have been three periods of eruption since the Middle Tertiary: (1) That of basic andesites, terminating in outpourings of rhyolite. (2) That of spongy porous rocks and ashes, marking the beginning of a tranquil period. (3) That of the basalts, continuous with Quaternary volcanic eruptions in various parts of the Sierra. The second period was marked by circulation of thermal waters in the fissures leading to the deposition of quartz with the sulphides.

The intimate structure of the veins, their variations in relation to the adjacent rocks and to each other, as well as the distribution of ores, are considered in a chapter by the same authors. Sanchez contributes a mathematical discussion of the fracture systems, arriving at practically the same conclusions with Daubree. Ordoñez gives results of investigation of the rocks microscopically, which are illustrated upon a plate. Other chapters by Sanchez, Rangel and Castro discuss the more purely economic features, exploitation, drainage, machinery and metallurgical methods in such a way as to be serviceable to those for whose special advantage they were written.

The volume is creditable alike to the authors and to the Minister of Internal Affairs, who has encouraged the expansion of the work.

J. J. STEVENSON.

Geologic Atlas of the United States, Folio 34. Buckhannon, West Virginia, 1897.

This folio consists of a descriptive text, a topographic map, a sheet of areal geology, one of economic geology, one showing structure sections, and finally a sheet giving a generalized section and table of synonymy. The authors are Joseph A. Taff and Alfred H. Brooks.

The quadrangle comprises an area of 931½ square miles and for the most part is located in the Appalachian coal field near the center of West Virginia, between latitudes 38°, 30′ and 39° and longitudes 80° and 80°, 30′. It embraces portions of Lewis, Upshur, Randolph, Webster, Braxton and Barber counties. The southeastern corner of the quadrangle lies in the district of parallel ridges which characterize the western border of the Great Valley, or central division of the Appalachian province. Rich and Mill, Back Fork, and Point mountains, which attain elevations or more than 4,000 feet, are the principal border ridges here mapped. From these elevated ridges the surface, an inclined peneplain, falls away toward the northwest, down to an elevation of near 1,700 feet. Six rivers have their sources within this quadrangle, West Fork of Monongahela, Buckhannon, Middle Fork, Valley, Little Kanawha, and Elk, all belonging to the Ohio drainage. These rivers, having their powers of corrasion augmented by the elevated and tilted surface of the country, have dissected the once nearly first country by deep, narrow channels.

The stratigraphy column makes a section of about 4,600 feet of rock. Sixteen hundred feet of interstratified Devonian sandstone and shale are divided nearly equally between the Jennings and Hampshire formations. Of the Lower Carboniferous there are about 1,100 feet, of which less than 100 feet is Pocono sandstone; 350 feet of Greenbrier limestone, and 650 feet of red shale, brown sandstone and conglomerate, making the Canaan formation. The remaining 1,900 feet comprises the coal measures known in this folio as the Pickens sandstone, Pugh formation, Upshur sandstone and Braxton formation, which are composed of conglomerate, sandstone and shale with beds of coal.

The structure of this district is typical of the two provinces which it includes. In the southeastern portion, east of Rich Mountain, the structure is that of the folded region of Great Valley, which is characterized by long parallel anticlines and synclines with north-southwest axes. West of Rich Mountain the typical Cumberland Plateau structure prevails. Here the strata are slightly inclined and gently folded.

The only product of economic importance is coal, of which there are seven workable beds. Two of these occur in the Pickens sandstone, three in the Upshur sandstone and two in the Braxton formation. The coals are from two to six feet thick. They have not been worked on a commercial scale, because other areas of productive coal lie between this field and the seaboard and nearer to large centers of coal consumption, both north and west.

On the economic sheet of the folio structural contours at intervals of 100 feet are represented by white lines. These, as drawn, represent the inequalities of the upper surface of the principal coal bed in the Upshur sandstone. The thickness of the strata being known, it is evident that the position of any other coal seam or bed may be determined from this datum plain.

Laboratory Manual of Inorganic Chemistry. By RUFUS P. WILLIAMS, in charge of the Chemical Department of the English High School, Boston. Boston, Ginn & Co. 1896.

This book, which is intended especially for use in elementary schools, is arranged so that each page is devoted to a separate topic. The alternate pages are left blank for notes and the experiments are unusually full of minute directions. This minuteness of directions may be well in the case of one who is working alone and can use the book to aid him in difficulties; but when working under the eye of the instructor it is questionable whether such close attention to details given in the book and, as in this case, working by rules is not apt to make the student too dependent, instead of teaching him to observe for himself and to devise, to a certain extent, the methods of work he shall follow in each experiment. The free use of symbols in other than equations is especially objectionable in the early stages of the study, as the student becomes impressed with the idea that proficiency in the use and manipulation of chemical symbols is the thing to be acquired and not the principles of the subject. Difficulties encountered and overcome by the ingenuity of the student are a great incentive and give him confidence in his own powers. After taking up in order the common non-metallic elements, the author gives the usual methods of separating the members of the different groups of metals. These are given without any preliminary study of the different members of the groups, which would enable one to understand the principles upon which the separations are based and must be entirely mechanical in their nature. No text-book is recommended for use with this laboratory guide, and while it can probably be used with good results in many cases it must be with the constant attention of the teacher and the elimination of some features, especially the part relating to the separation of the metals.

J. E. G.

Elements of Chemistry. By RUFUS P. WILLIAMS, in charge of the Chemical Department of the English High School, Boston. Boston, Ginn & Co. 1897.

The title of this book is rather a misnomer, as the author has gone beyond the capacity of an elementary student and has introduced much matter which would only bewilder a beginner in the subject. As he says in the preface, 'the division of matter into coarse and fine print enables a choice to be made' according to the needs of the class. He is a strong advocate of graphic methods of representing compounds, and 'and many topics—such, for example, as valence, etc.—have been treated in quite an original manner.' On turning to this chapter we find that he represents valence graphically 'by using cubical kindergarten blocks with small screw-eyes and hooks' to represent the bonds and their method of attachment. Before studying the simplest element he instructs the student in the methods of writing symbols and finding molocular weights by rule. The subject, omitting the theoretical part, is treated in a very thorough manner for an elementary book; but the arrangement, especially that of the non-metals, is not as systematic as it might be. The latter part of the book contains an account of some common organic substances and a chapter on the chemistry of fermentation and of life.

J. E. G.

Congreso Internacional de Americanistas. Actas de la Undecima Reunion, Mexico, 1895. Mexico, 1897. 1 Vol. Pp. 576.

The previous volumes of the International Congress of Americanists all contain some valuable articles and all a good deal of trash. In both these respects the present Compte-rendu resembles its predecessors. Why people who pretend to be scholars still want to publish articles showing that the name of the Atlas mountains is derived from the Nahuatl 'Atlan;' that the Otomis are related to the Chinese; that the cross of Palenque is a proof of Buddhistic

worship in America; that the 'Toltecs' spooked around Central America; that the fables of the Aztec story-tellers can be assigned local existence, and the like, is hard to understand; and why a scientific society spends its money in publishing such stuff would be more inexplicable did we not all appreciate the importance of not offending the genial members of such reunions.

Fully half this volume is taken up with such padding and with second-hand material. Rather than occupy the reader's time with a discussion of it, it will be more profitable to mention some of the really valuable contributions to American studies, which are between the covers of the nearly six hundred pages.

Naturally we look for special attention to the Nahuatl language. Nor are we disappointed. The Rev. Hunt Y. Cortes, distinguished by his previous studies in this tongue, offers a number of specimens of the classical idiom, with excellent analyses and grammatic observations; Don José Maria Vigil called attention to the ancient Mexican songs still extant, and Don Mariano Sanchez Santos, an accomplished Nahuatl scholar, gave translations of several of them. Lauro Castanedo sent copies of a few old religious manuscripts in a dialect, evidently corrupt, of the ancient tongue. Other linguistic memoirs are presented, one from Dr. Pimentel, on the present classification of the Mexican languages; a catalogue of periodicals published in North American native tongues, by Sr. Cesare Poma; a valuable grammatical sketch of the Guaraouno tongue, by M. L. Adam; two by M. Raoul de la Grasserie, on the Auca and the Yunga; a comparison of the Huasteca and Nahuatl, by Alvarez y Guerrero, and several rather wild flings at the derivations of some native names.

The only contribution of moment offered to the study of the hieroglyphic writing was a paper by Dr. Nicolas Leon on the employment of a script of the kind, of course devised by their European teachers, among the Otomis, in a period long after the Conquest. We learn from this memoir that the spiritual fathers did all they could to keep the Indians in ignorance of white civilization, and thrashed them if they tried to learn Spanish!

The papers on the ancient monuments are moderately full. Señor Rodriguez describes the pyramid of Tepozteco at length, and Mr. H. S. Jacobs, in a somewhat flowery style, runs over the cliff-dwellers and the 'dead empires, the wonderful evidence of prehistoric life, to be found in Mexico!'

Some minute questions in Mexican history are elucidated, and Mr. Thomas Wilson advances various reasons showing the great antiquity of man in America. Professor Mariano Barcena submits again the evidence for the prehistoric man of the valley of Mexico, our old friend, the 'Hombre del Peñon,' about whom our departed colleague, Professor Cope, became skeptical in his latter days.

There are some other articles in the volume, good in the way of compilations; one on the media of exchange of ancient Mexico, by Mr. J. W. Bastow; one on the ancient commerce of Yucatan, by the late Bishop Carrillo Ancona; on the medical knowledge of the Aztecs, by Alatriste de Lope; and others of minor importance.

Although the scientific value of the volume may be disappointing, the foreign associates were unanimous in their sincere recognition of the generous hospitality they received from the Mexican government and citizens; and it is very creditable to the Committee of Publication that the volume has appeared thus promptly, while the report of the Congress in Stockholm, in 1894, to employ a Gallicism, still 'lets itself be waited for.'

D. G. Brinton.

Totem Tales. W. S. Phillips. Chicago, Star Publishing Co. 1896. Pp. 326.

The present book pretends to be a collection of myths from the coast of the North Pacific Ocean. The author says: "The stories contained in this little volume under the title of 'Totem Tales' are the result of careful study and research among various tribes of Indians of the Northwestern Pacific Coast. The Indian peculiarity of narration is kept, as nearly as possible, consistent with an understandable translation from the native tongue into English." If it were not for these claims the book might pass unnoticed, but since the author's expressions might be taken seriously it may be well to

sound a note of warning. Nothing can be less Indian than the words in which the tales are couched, nothing more misleading than the illustrations which represent the Indians of the coast as living in tepees and dressed in the style of Indians of the plains. The few sketches of Indian masks and paintings are given fanciful interpretations. Most of the stories are highly modified versions of stories from the region between Columbia River and Alaska, but the author has also introduced the Sedna legend of the Eskimo of Baffin Land (see Sixth Annual Report Bureau of Ethnology, p. 583 ff.) under the title 'Cawk, the Beaver's Daughter.' The figures representing the thunderbird (pp. 286 ff.) have been taken from the Tenth Annual Report of the Bureau of Ethnology (p. 483) and belong to a variety of tribes. As a representation of Indian life and thought the book is entirely misleading.

FRANZ BOAS.

SOCIETIES AND ACADEMIES.

THE NEW YORK SECTION OF THE AMERICAN CHEMICAL SOCIETY.

THE regular November meeting of the New York Section of the American Chemical Society was held on the 5th, at the College of the City of New York. A paper on 'Corrected Assays' was read by E. H. Miller, and on the 'Chemistry of Formaldehyde in Disinfection with Exhibits' by Dr. E. J. Lederle.

Apparatus was exhibited for the production of formaldehyde in house disinfection, and an active discussion followed on its chemical properties, methods of estimating strength of solutions, effects of impurities, etc. It was stated that none of the so-called 40% solutions contain more than 33 to 36% of formaldehyde, and on account of the numerous impurities the specific gravity is no guide to the strength of the solutions. Its combination with glue was said to be perfectly stable, and if once thoroughly dried, perfectly insoluble.

A paper on the 'Chemistry of Substance used in Perfumery' was announced for the next meeting, and an interesting exhibit of natural and synthetic products is anticipated.

DURAND WOODMAN,
Secretary.

NEW YORK ACADEMY OF SCIENCES—SECTION OF ANTHROPOLOGY AND PSYCHOLOGY.

THE Section meets bi-monthly at the Mott Memorial Library. The first meeting of the fall was held Monday evening, October 25th. Professor Cattell presented a report from the pen of Professor A. C. Haddon, of England, on Anthropology at the Toronto meeting of the British Association, and Dr. A. Hrdlicka reviewed the work in Anthropology and Psychology at the American Association.

Dr. Franz Boas and Dr. Livingston Farrand made a preliminary report of their work during the summer on the Jesup expedition sent out by the Museum of Natural History.

Their work was mainly among two of three tribes in the western part of British Columbia. Many interesting details were brought out with reference to tribal organization, language, customs and traditions. Attention was called to the rapid changes going on as a result of their location upon government reservations.

The general plan of the work undertaken by the Museum was outlined by Dr. Boas. It will extend over a period of years and will include an exhaustive study of the tribes on the northeastern coast of Asia as well as all the remaining tribes on the northwestern coast of America.

The next meeting of this section of the Academy will be held on the last Monday in January.

C. P. BLISS,
Secretary.

RESULTS OF THE BERING SEA CONFERENCES.

THE Fur-Seal Conferences recently held at Washington by representatives of the governments of Great Britain, Russia, Japan and the United States are noteworthy in several respects. The high character and fitness of the delegates, the rapidity with which the negotiations were carried to a successful conclusion, and the essential agreement reached on the principal points under discussion, are matters for international congratulation. It will be remembered that Great Britain declined to take part in a joint conference in which Russia and Japan were to be represented. This led to the holding of two distinct conferences—the first with Russia and Japan; the second with Great Britain and Canada. In the first there were few if any points of dispute, and an agreement was promptly reached whereby the governments of the United States, Russia and Japan pledged themselves to desist from pelagic sealing for a period of one year, pending subsequent negotiations.

In the second conference the conditions were entirely different, the matters under discussion between Great Britain and the

United States having been the subject of international controversy for a number of years. It will be remembered that both countries have been represented at the Pribilof Islands by experts during the past seven years, and that the members of the original Bering Sea Commission of 1891 (Professor T. C. Mendenhall and Dr. C. Hart Merriam for the United States; Sir George Baden Powell and Dr. George M. Dawson for Great Britain) failed to agree on the facts of seal life at the islands. It will be remembered also that in subsequent years the reports of the experts representing the two countries differed materially as to the condition of the rookeries and habits of the seals. These facts, in connection with the hostile attitude of the press of the contending countries and the anxiety over the outcome felt by both governments, give to the findings of the conference an interest and importance quite out of proportion to the real weight of the points at issue.

Great Britain was represented by Professor D'Arcy W. Thompson, of Dundee; Canada, by Mr. James M. Macoun, of the Canadian Geological Survey; the United States, by Dr. David Starr Jordan, President of Stanford University, and the Honorable Charles S. Hamlin, formerly Assistant Secretary of the Treasury. The conference was notable for its brief duration (the sittings occupying only seven days) and for the essential accord of the scientific experts respecting the numbers, condition and habits of the fur seals.

The case was one where naturalists of reputation, who had personally studied the fur seals at the islands, were called upon to make a joint report on matters that had been in controversy for many years, that had led to strained relations between the governments concerned, and respecting which diverse opinions prevailed among the people and the press. The important fact must not be overlooked that the people and the press of Great Britain and Canada have not up to the present time understood the real facts in the case, and that in combating the attitude of the United States they have done so largely through misinformation. It is important to bear in mind, therefore, that the British and Canadian experts in signing the joint report are liable to incur the displeasure of their countrymen, who may regard the report as a concession to the United States. The greatest credit is due them for making a straightforward statement of fact, irrespective of public prejudice.

The delegates had no power to recommend remedial legislation, their duty being to submit a joint report on the facts on which they could agree as to the condition and habits of the fur seals. With these facts before them, it is hoped that the two governments will find little difficulty in framing measures necessary for the permanent protection and preservation of the seal herd. That such measures involve the ultimate cessation or limitation of pelagic sealing is a fair inference from the report of the expert delegates. That Canada, having no rookeries of her own and consequently no opportunity to profit by the sealing industry except as carried on in the open sea, will voluntarily relinquish pelagic sealing without some offset or concession on our part, can hardly be expected. The

friendly attitude of the two governments as shown by recent events leads to the hope that the whole matter may be amicably adjusted. In any event, the complete agreement of the naturalists taking part in the conference may be regarded as a triumph for science.

The essential features of the propositions agreed upon are as follows :

That since 1884 the Pribilof herd has declined from year to year until at present the number of seals is not more than one-fifth to one-third as great as formerly, although the number of breeding females in 1896 and 1897 was between 160,000 and 130,000. It is also agreed that there has been a notable decrease since 1896, although the exact amount of this loss could not be determined. The existence of a high death rate among the young from natural causes is acknowledged and the conclusion reached that not more than one-half or one-third reach the age of three years.

To those who are acquainted with the various reports on the subject the latter figure will seem nearest the mark, and the evident inference would be that if the death rate in nature is so great any addition to it by such causes as pelagic sealing, with the consequent starvation of thousands of young, is bound to reduce the seal herd. The methods of driving and killing as practised on the islands, it is stated, call for no comment, and it is admitted that land killing as now carried on does no harm.

This is one of the points on which the press of both England and the United States has been more or less confused and, in spite of all that has been written on the fur seal during the past few years, there seems to be a vague suspicion that after all land killing may have had something to do with the decrease of the herd. This matter was fully discussed in the preliminary report of 1896, where it was very clearly shown that as the fur seal is polygamous and the harems even now, when the number of females has been greatly reduced, contained on an average thirty females to one male, it is evident that, the birth rate being equal, there is a vast superfluity of males.

It is acknowledged that the catch at sea contains a marked excess of females, and this is a most gratifying admission to those who have read the statements made by the sealers, in which the number of males taken was frequently reported to be as great as that of the females and sometimes even greater, a remarkable state of affairs when it is remembered that, owing to the killing of young males on land and the fact that the nursing females are compelled to go to sea in search of food at a time when the males are on shore, the females are bound to be greatly in the majority.

On the other hand, it is pointed out that not all these females are nursing or pregnant, for the reason that many adult seals have lost their pups through the natural causes, while a certain percentage is bound to consist of yearling and two-year-old females.

The conclusion that excessive pelagic sealing has lead to a decrease in the herd is coupled with the axiomatic statement that a small number of females, less than the annual increment of breeders, might be taken without producing actual decrease.

As this annual increment is at the best small and as for ten years there has been a steady loss, it seems apparent enough that the number that might be taken with safety has been very much exceeded.

It is conceded that pelagic sealing has of late fallen off in a greater ratio than the herd, thus producing a tendency toward equilibrium in numbers. This simply means that over 60,000 seals were taken in 1895; 43,000 in 1896, and 26,000 in 1897, so that the pelagic catch has fallen off one-half in three years, although the herd has not diminished by one-half in the same time.

It is to be feared that before any equilibrium could be reached but a small portion of even the present number would be left, and this leads naturally to the next point agreed upon, which is that in estimating the future conditions of the herd the reduction in the number of pups caused by the pelagic catches of 1894 and 1895 must be taken into consideration.

For example, not less than 20,000 pups, half of them females, perished of starvation in 1895, owing to the death of their mothers from pelagic sealing. Not only did the portion of this number that would have survived fail to appear on the rookeries in 1897, but the number of births will be naturally lessened by just that number in 1898 and the progeny of these in turn fail to appear in 1900. Thus, as the natural decrease will go on, while the natural increase has been cut off, effects of pelagic sealing will be felt up to 1900, even should it be stopped at once.

The final conclusion is that the herd is not in danger of actual extermination so long as its haunts on land are protected and the protected zone about the islands is maintained, and that both land and sea killing now yield an inconsiderable profit. The seal herd is in fact very far from actual extermination, although the point of commercial extermination, or that where the returns are wholly incommensurate with the amount of capital invested, has been nearly reached. But for the prompt action of the United States in 1869 this point would have been reached years ago, while but for its care of the islands ever since practical extermination would not be far off.

The example of the Southern fur-seal illustrates the rapidity with which commercial extermination may be effected, while the fate of the fur seals on the Farallones, Guadalupe and Juan Fernandez shows how readily actual extermination may take place. The Pribilof Islands are not, like those of the Antarctic, difficult of access, and their abandonment by this government would lead to the actual extirpation of the fur seals within a very few years. On the other hand, with proper protection the fur-seal herd can, with but little care and cost, be made an important source of revenue so long as fashion may decree the wearing of of seal-skin sacques.

THE PSYCHOLOGY OF THE PERSONAL EQUATION.

In the present paper the writer proposes to maintain the thesis that the personal equations of astronomers are mainly controlled by known laws of experimental psychology and hopes to assist his professional brethren in making use of the researches of the psychologists in such a manner that they shall avoid groundless hypotheses

which have often been harmful by leading to premature conclusions and thus have hindered the progress of our knowledge.

I do not wish to be considered as denying the possibility that the psychologists may learn something from the steady and well understood routine of the astronomers in their practical operations. In truth, almost the first step towards the measurement of the times occupied by mental processes was taken by the great astronomer Bessel in his classical memoir on 'Personal Equation,' which is reprinted in the third volume of Engelmann's edition of his 'Abhandlungen.' Bessel indicated there very clearly that the cause of the riddle which he partially solved was a psychical one, namely, the impossibility of comparing the impressions on two senses, sight and hearing, which take place exactly at the same instant. The 'eye and ear' observer who uses Bradley's method as modified by Maskelyne in noting down the time when a star image passes a fixed thread in his telescope makes the attempt to combine these two impressions, and in so doing necessarily 'apperceives' one of them before the other, and this produces 'personal equation,' or constant error in the time, which in seconds and fractions he notes down in his observing book. Bradley, in his journals of observation, noted vulgar fractions of the seconds. Maskelyne, Bradley's successor, failed to discover even the facts of personal equation, except in the work of one of his assistants. This case, that of Kinnebrook in 1795, was apparently settled by discharging the poor fellow as irregular and 'vitious' in his methods of observing. The personal equations of Maskelyne's other assistants were not known till many years later; Bessel's discovery, made about 1820, originated in his reading Maskelyne's notes about Kinnebrook's apparent want of skill. After the publication of Bessel's memoir the matter was followed up by W. Struve, Airy and other eminent astronomers, before the invention of the chronograph in 1849 had become the common property of astronomers. It led very soon to the thought that something similar had place in chronographic registration. This suspicion was fully confirmed before or soon after the 'American Method' was introduced at Greenwich.

In 1861 the psychological side of the investigation was taken up by Professor Wundt and led to the important discovery of the displacement of time when the observer attempts to fix the place on a divided scale of a continuously moving object. This displacement of time can lie in either direction, and thus an apparent difficulty is relieved which arises from the facts of personal equation as observed by Bessel, W. Struve and Argelander, and also by the astronomers who took part in Struve's chronometric expeditions of 1843 and 1844. The regular Greenwich investigations began with Airy's entrance upon the office of Astronomer Royal, in 1835, and have been continued to the present day.

The attempts by means of personal equation machines to determine the absolute personal equations of eye and ear observers led to the general result that most observers anticipate the true time of the transit, and that those who, like Argelander, fall behind it are fewer in number. If we take the average observer as the standard, as Sir George Airy seems to have intended, we find but few of those tested between 1835 and 1859 who fell behind the standard observer for the time, or behind the average of the body of observers in employment together at Greenwich. In my paper in the *Monthly Notices* of the Royal Astronomical Society for May, 1897, I have shown that the Greenwich observers since 1885 have anticipated their own times of chronographic transit by an amount not far from $0^s.13$, on the average. One excellent observer,

Mr. Hollis, anticipates his own chronographic transit by $0^s.5$, and does this, not because his eye and ear anticipation of the true time is very large, but because he employs the slower method of registration, first pointed out, if I mistake not, by Le Verrier, and his chronographic transits are about $0^s.2$ later than those of the average observer. The difference $0^s.13$ between the average observer's eye and ear transits and chronographic is about the average time of a 'simple reaction' according to the psychologists, and thus its amount confirms Wundt's view that chronographic registration by a practiced observer is closely analogous to the process of simple reaction. We thus reach the conclusion that the anticipation of such an average observer, added to the positive time which he requires to make a registration, is but $0^s.13$, and a partial compensation would take place if the two methods were used in connection. The best form of personal equation machine is, as it appears, the Repsold Transit Micrometer. The tests which have been made of it, as of other contrivances for a similar end, are not entirely conclusive for various reasons, and the chief of them in this case seem to arise from the novel construction of the instrument and the short experience of the observers with it.

I quote from the *Astronomische Nachrichten*, No. 3,036, the following differences chronograph-Repsold Micrometer for Professor Becker and his colleagues :

	Chronograph-Repsold Micrometer.	Mean Error.
Becker	$+ 0^s.319$	$\pm 0^s.009$
Halm	0.224	0.009
Kobold	0.110	0.011
Zwink	0.158	0.016

These personal equations are of the same general order of magnitude as the reaction times found by a multitude of psychological experimenters. The largest differences among them may without much danger be ascribed to the same cause as the chronographic personal equation between Mr. Lewis, now standard observer at Greenwich, who employs the quicker method of registering, and Mr. Hollis, who employs the slower; their average differences for ten years is $0^s.24$, varying very little from year to year, and that between Dr. Kobold and Professor Becker is $0^s.209$ by the data given above and $0^s.255$ by direct chronographic registration. The former registers rapidly and the latter slowly, but they do not give in the article cited any account of their psychical process.

Wundt, in his classical work 'Grundzüge der physiologischen Psychologie,' expresses the decided opinion that astronomers will do well to study the methods of the psychologists in dealing with personal equations, and this conviction I venture to consider as confirmed in a definite numerical way in my paper in the *Monthly Notices* to which I have referred. Additional arguments in favor of the psychological conclusion are not wanting and will be briefly stated. In the first place eye and ear observers note the times of transits differently when they observe stars on different sides of the zenith. There does not appear to be any certain general rule as to the sign of this form of equation. Chronographic observers register transits of time stars about $0^s.02$ or $0^s.03$ later when the direction of motion is opposite to the usual one. This agrees with the psychical law that unfamiliar circumstances tend to delay reaction. Faint stars are observed by chronograph later than brighter ones. This delay, about $0^s.013$ per magnitude, has been tested by several of the most eminent observers now living and found to increase in amount as the stars approach that magnitude at which they are observed with difficulty by a given transit instrument. A similar delay in reaction to a sense impression, not a linear function of the intensity of the sense

impression, is found to be shown when the sense impression is faint. Even the amount $0^s.013$ per magnitude is approximately indicated by the experiments of G. O. Berger and Professor Cattell, who have found, for a diminution in intensity to one-thousandth of its normal amount, a delay in the reaction to impressions on the sense of sight by $0^s.113$ for himself as reagent and $0^s.108$ for Dr. Cattell. The diminution in intensity corresponds to seven and one-half magnitudes on the usual astronomical scale: $7\frac{1}{2}=\log. 1000 \div 0.40$ and the quotients $0^s.113 \div 7\frac{1}{2}$ and $0^s.108 \div 7\frac{1}{2}$ are approximately $0^s.013$.

The eye and ear transits of very faint stars are liable to singular variations of personal equation; sometimes they are noted relatively too late and sometimes too early. Argelander suspected this last variation for himself and Auwers has proved it, and Argelander's explanation fits the phenomena as observed. He considers that according to Bessel's theory he 'first saw' and 'then heard,' but that when the star was very faint this displacement of time was reversed in direction. For stars not below the limit of magnitude where observation is easy this reversal did not take place. Auwers has shown that in similar cases Bauschinger observed very faint stars too soon by about one-tenth of a second of time. The reversal in Argelander's case produced a variation a good deal larger for extremely faint stars than Bauschinger's, but for either observer the fact of reversal is highly probable. In my paper before cited I give only a part of the details of the Greenwich observers' two-method personal equations. Those details which I do give indicate very clearly that the two-method personal equation varies from year to year, as had been previously found by Dr. Hilfiker, A.N., No. 2815. For example, Mr. Crommelin anticipated his own chronographic transits by $0^s.20$ in 1892 and by $0^s.10$ in 1893. Mr. Bryant by 0.07 in 1892 and $-0^s.01$ in 1893. Similar variability from year to year is indicated in the work of the veteran observers, H.T., A.D., T.L., and H., for whom only average values are given in my paper. Nor are such alterations of personal equation confined to the eye and ear personal equation or its difference from the chronographic. Professor Turner, Chief Assistant, anticipated Mr. Downing with the chronograph by $0^s.15$ in 1886 and by $0^s.08$ in 1888. Mr. Lewis, now 'standard observer,' anticipated Mr. Downing by $0^s.01$ in 1886 and $0^s.10$ in 1891, and similar changes are visible in the eye and ear personal equations relative to the standard observer of the year. The instrument and stars were essentially the same for all the years between 1885 and 1893, so that the changes in the two-method personal equations are psychical variations in the habits and methods of registration and of noting eye and ear transits. The study of these habits and methods is plainly a branch of experimental psychology. We have already obtained some indications of how astronomers can promote this branch of study to their professional benefit as well as to that of psychological science. The simplest way for them to proceed is first of all to make more extensive comparisons of the eye and ear and chronographic method than have already been accomplished. Such comparison of eye and ear and chronographic transits of stars of various magnitudes would with little trouble extend our knowledge of the subject to a considerable degree. The Greenwich astronomers have detected the 'Gill equation' in chronographic transits; especially with the altazimuth. The same form of personal equation has been found in Professor Küstner's Berlin observations and by Mr. Tucker, of the Lick observatory, in his own. The 'Helligkeitsgleichung' for chronographic transits is, as before stated, already well

known and exhibits some uniformity. The great observatories which still so effectively employ the eye and ear method have a wide field of investigation open to them for the places of unknown stars which are not too faint to be more advantageously observed by eye and ear than by chronograph. Of course, immediate micrometrical measurement would give us enough material for completely settling the 'Helligkeitsgleichung' for most living astronomers. Stars within five degrees of either pole can now be observed by the Greenwich method, and the doubts and perplexities which hinder the accurate study of their right ascensions will soon vanish.

The Repsold micrometer, already an indispensable tool in determinations of longitude, is not well enough known to enable the observers to omit the exchange of their own stations and instruments.

But the numbers obtained by its use cannot, I suppose, yet be called absolute personal equations, but from them I venture to guess that the difference between the largest 0.319 for Professor Becker and the smallest 0.110 for Dr. Kobold implies that Professor Becker employs the sensorial or deliberate form of registration and Dr. Kobold the motor or shortened form; as the difference between them, $0^s.209$ with a mean error of 0.014, is nearly equal to that of $0^s.24$ between Messrs. Lewis and Hollis at Greenwich from eleven years' comparisons, 1883–1893.

The conclusion which some astronomers appear to favor, that by Bradley's method, as well as by the chronographic, faint stars are observed relatively later than brighter ones, is shown not to be a safe one, because we have cited two examples of thoroughly skilful observers who observe very faint stars earlier than those whose observation by eye and ear is easiest and most accurate. There is also a series of 'Coefficients of the light equation collected by Professor Auwers in his Berlin Zone of the A. G. C.,' in which there is so little uniformity even as to sign that he is led to remark upon the uncertain and fragmentary nature of the results in this matter; so far as obtained by astronomers. If the eye and ear observer is careful not to observe transits of stars too faint to be seen in the illuminated field, we are partially justified in concluding with Bauschinger that the 'Helligkeitsgleichung' is not then a sensible form of personal equation for eye and ear work, and we can also conclude that it deserves attention chiefly in its psychical aspect and that the method of making good eye and ear observations of transit is to make sure by ingrained habit of the uniformity of the psychical process from star to star, especially when the attempt is made to determine the right ascension of faint stars like the fainter ones of the 'Durchmusterung.'

The writer is not aware that any other astronomer has made the attempt to compare the numerical results of the psychologists with the personal equations as determined in the usual routine of observatory work, and is inclined to recommend the continuance of such comparisons in directions which at once suggest themselves.

First. Comparisons of eye and ear and chronographic transits of stars in various magnitudes and declinations.

Second. Comparisons of observations by both methods with the Repsold Transit Micrometer.

The subject of this paper is so broad and goes so deeply into many problems of practical astronomy where high accuracy is aimed at that the writer can only express regret that his attempts to deal with the matter have been so inadequate, and hopes that at a future time he may be able to prosecute it farther by the kind assistance of his colleagues and pupils.

TRUMAN HENRY SAFFORD.

WILLIAMS COLLEGE,
WILLIAMSTOWN, MASS., August 1, 1897.

THE PROGRESS AND ACHIEVEMENTS OF HYGIENE.*

HYGIENE is a department of medicine whose object is the preservation and promotion of health and deals, therefore, with all the various factors likely to influence our physical welfare. It is not an independent science, but rather the application of the teachings of physiology, chemistry, physics, meteorology, pathology, statistics, epidemiology and bacteriology to the maintenance of the health and life of individuals and communities. The subject is very properly divided into personal and public hygiene. In the former the doctrines are applied to individuals, in the latter to communities.

This branch of medicine has received such an impetus within the last twenty-five years that many persons regard it of modern origin; such, however, is not the case, for on turning to early history we almost invariably find that the health of the population has been made a subject of legislation. Hygiene was practiced by the Egyptians, who paid special attention to their diet and the care of children; they knew the dangers of floods to health, and resorted to preventive measures against their occurrence, as well as against the spread of contagious diseases.

The old Indians paid special attention to diet, habitation, exercise and the isolation of children in case of infectious diseases. The Mosaic code of laws contains minute directions for the cleanliness of the person, the purification of the dwelling and camp, the selection of healthy and avoidance of unwholesome food, the seclusion of persons with contagious diseases, the regulation of sexual functions, etc. The sanitary code, especially that part which relates to the slaughtering of animals, the food supply, its preparation, care of utensils for cooking, eating and drinking, personal cleanliness and frequent ablutions of the hands, appear peculiarly appropriate, since our knowledge of infectious disease germs, and it is a singular fact that, from some cause or causes, this race presents an endurance against disease that does not belong to other portions of the civilized communities amongst which its members dwell.

This resistance dates from the first to the last periods of life. Hoffmann finds that in Germany the number of still-born amongst the Jews was 1 in 39, and of the other races 1 in 40. Mayer determined that Hebrew children from one to five years of age die in the proportion of 10% as against 14% among the Christian children. After the fifth year the value of life still continues in favor of the Jews; the average duration of the life of the Jew being 48 years and 9 months, and of the Christian scarcely 40 years. In the census statistics of 1890, Dr. Billings has investigated the subject and developed the fact that the death-rate among the Jews in our own country is very low, being only 7.11 per 1,000, a little more than one-half the annual death-rate among other persons of the same social class and conditions of life, but the facts of most interest brought out are the low marriage rate, 7.4 per 1,000, as compared with 18 to 22 per 1,000 among the general population, and the low birth-rate, which was 4.66 for each mother. The number of Jewish children under 5 years of age in this country is therefore less, being in the proportion of 9 to 13, of the average population, but from 5 to 15 years it is greater in the proportion of 29 to 23. The causes for the higher vitality of the Jewish race have been earnestly searched for, because that race which presents the strongest vitality, the greatest increase of life and the longest resistance to death must in course of time become dominant. The causes may be summed up in the term

* Read before the Anthropological Society, Washington, D. C., May 4, 1897.

'soberness of life.' The Jew drinks less than his Christian brother; he takes as a rule better food; he takes better care of his poor and he takes better care of himself. How much his sanitary code of laws has accomplished in this direction I will not undertake to estimate.

A study of the habits of the primitive peoples in different parts of the globe shows that a desire to prevent disease is innate to all men. Among matters of personal hygiene may be mentioned massage for the purpose of overcoming fatigue, ocean, river, hot-air and vapor baths as practiced among many Indian tribes, the employment of eye-protectors against the glaring effects of snow among the inhabiants of the Arctic region, the use of respirators by the Kwixpagmut, an Eskimo tribe, to prevent the inhalation of smoke during their sweat baths. (Max Bartels, p. 222).

Many of our North American Indians have their medicine dances, the chief object of which appears to be the preservation of health. Thus the men of the Nez Perces tribe, between the ages of 18 and 40, assemble annually for the purpose of conquering 'Mawisch,' the spirit of fatigue; the ceremony lasts from three to seven days, and consists in the introduction of willow bougies into the stomach, followed by hot and cold baths and abstinence from food. The Indians are of the firm belief that they secure thereby increased strength and power of endurance (Bancroft), and I see no reason why a perfect cleansing of the body and temporary fasting should not result in a thorough purification of the blood and tissues, a more perfect metabolism and increased nutrition and power of resistance of the individual cells.

The disposal of the dead by cremation, and the destruction of the tepee and personal effects by fire after fatal cases, is a practice in vogue among a number of Indian tribes, and are worthy of mention, as fire is the best known germicide. Many of these primitive peoples appear to have correct ideas as to the communicability of certain diseases. Ehrenreich tells us that consumption prevails extensively among the Karayá in Brazil, and whenever a stranger approaches their huts he is asked whether he suffers from a cough, and unless the answer is negative he is not admitted—a very suggestive precept in view of the fact that scientific medicine has established the infectious character of tuberculosis. Pallas writes that the Kirgise during small-pox epidemics do not hesitate to use their arrows if necessary to keep infected subjects from entering their homes. In passing I may remark that such a brutal system of quarantine was practiced only last year in our country. A man suffering from small-pox was expelled from Arkansas and refused admittance into Mississippi. As he could not remain in or on the Mississippi River until the disease ran its course, he attempted to evade the quarantine and land on the river bank in the latter State, but was shot and killed by one of the quarantine officers.

As an example of public health measures may be mentioned the fact that Harmond, during an expedition to Mé Không, in Farther India, in the land of the Khâs, found, suspended outside of all villages which had been previously visited by cholera, a piece of wood, carved with a sign language to the effect, "Whosoever dares to invade our palisade during the next twelve days will be imprisoned and must pay a fine of four buffaloes and twelve ticals;" the sign on the reverse side gave the number of men, women and children in the village. The same observer noticed that the inhabitants of villages occupied by the Attapeu, which are close neighbors of the tribe of Laotes, laid pieces of lumber in the form of a star across their roads and paths, or suspended similar signs with bunches of leaves with-

out the gates of their settlement, to warn strangers of the prevalence of an epidemic among men or beasts within. The natives of the island of Keisar interdict marriage with lepers, evidently believing that leprosy is not contagious but is transmitted by heredity, while the natives of the Watubela islands believe the converse and transport their lepers to Gorong for isolation and treatment.

The practice of isolating contagious disease, especially during epidemics, appears to be quite common. Thus, at the island of Nias small-pox patients are sent to a temporary shelter outside of the camp and placed in charge of a relative, protected by a previous attack. The Traos of Cochin China, the Tunguse and Burates abandon their small-pox patients after providing them with boiled rice and water. Some of the Indian tribes in northern Mexico also abandon their contagious cases after placing water and wild fruits within easy reach.

But, to return to the Aryan race, we find that the Greeks and Romans, although not, like the Jews, making hygiene a part of their religious duty, paid special attention to the physical culture of their youth, endeavoring, by a rational care of the body, to promote the culture of their mind, and to secure freshness and energy, courage, presence of mind, grace and dignity. "The laws of Lycurgus," says Dr. Gardner, "are not wanting in very pointed enactments on sanitary matters, and the importance attached by all the Greek republics and in the Platonic ideal polity to physical culture is too well known to require further comment;" they paid, also, much attention to the water-supply, constructed numerous aqueducts, and Athens was provided with sewers at an early period of its history.

The teachings of Hippocrates, 400 B. C., doubtless bore many fruits, and whether it is true or not, as stated by Galen, that he ordered, during a pestilence at Athens, aromatic fumigation and large fires in the streets, we have at least his writings on air, water, soil, habitations and occupations and his views of local and seasonal influences on sporadic and epidemic diseases. In Homer's Odyssey reference is made to Ulysses purifying his house with burning sulphur, and Aristotle in his Politica shows his sanitary acumen when he says: "The greatest influence upon health is exerted by those things which we most freely and frequently require for our existence, and this is especially true of water and air."

The Romans, amidst their military operations, found time to construct the 'Cloaca maxima' about 2,400 years ago, which not only served for the removal of refuse, but also helped to drain many of the marshes, and constitutes the principal sewer of modern Rome. Aqueducts were made to cover miles upon miles of the surrounding plains, and their splendid ruins, many of which have been restored and are now used for their original purpose, attest the munificence and abundance with which the first of sanitary requisites was supplied to the Eternal City. At one time Rome had 14 large and 20 small aqueducts, some of which carried the water from a distance of 50 kilometers, and during the reigns of Tiberius and Nero the per capita supply was over 1,400 liters a day. It is stated that between 400 B. C. and 180 A. D. about 800 public baths were established, among them the 'Thermae Caracallæ,' which alone could accommodate 3,000 bathers at one time. It has often been charged, how justly I cannot say, that one of the first things the Christians did in Rome was to try to tear down the baths and convert them into churches; but when we see in our own midst the attempt to convert these useful institutions into abodes of vice, we can imagine how, with a licentious people like the Romans, their baths had degenerated into hotbeds of iniquity.

During the reign of the Cæsars attempts were made to drain the Pontine Marshes, sanitary officials and physicians to the poor were appointed and homes for poor girls and orphans were established. In the meantime the true spirit of Christianity asserted itself, and we read of the establishment of hospitals as early as the 4th century; these were speedily followed by infant and orphan asylums and homes for the poor and incurables. During the Middle Ages sanitation received a decided check, ignorance and brutal prejudices appear to have been the ruling spirit, and for many reasons it was the most insanitary era in history.

About this time most of the towns in Europe were built in a compact form, surrounded with walls; the streets were narrow and often winding for defensive purposes, shutting out light and air from the houses. The accumulation of filth was simply frightful. Stables and houses were close neighbors, human filth was thrown on the streets or manure heap. A city ordinance of Muhlberg in 1367 prescribed that manure deposited by householders on the market space must not be allowed to remain longer than 14 days. The dead were buried within the churchyards. Sewers and aqueducts having been permitted to fall into disuse, the inhabitants were compelled to resort to wells with polluted subsoil water. All the conditions were favorable for the spread of infectious diseases, and in the 14th century the Oriental pest or bubonic plague carried off in Germany over a million victims. Venice lost 100,000 and Florence 50,000 of its inhabitants; England lost one-half of its people, and London, then a city of 110,000 residents, buried over 50,000 in one cemetery. According to conservative estimates the deaths from this plague in Europe amounted to from 25 to 30 million people. The majority of people regarded the plague as the dispensation of God's providence, an evidence of divine wrath, which they hoped to allay by all sorts of self-inflicted punishments, and the passion plays of Oberammergau and elsewhere originated about this time. Others accused the Jews of being the cause, and hundreds were burned at the stake until Pope Urban IV. placed them under his special protection. The Faculty of Paris attributed the epidemic to the conjunction of planets on a certain day in 1345, and the Faculty of Leipzig, with equal gravity, asserted that it was connected with earthquakes, unseen waves of air, inundations, etc. Venice, alone of all Europe, took a sensible view of the matter, and for the first time in history, in 1348, appointed three guardians of public health, and the rules adopted later to isolate infected houses and districts for forty days has given rise to the term quarantine (from quaranta giorni).

We are told that this board rendered excellent service in matters relating to public sanitation, the control of markets and the sale of unwholesome foods, etc., and also inaugurated a system of mortality reports with columns for the insertion of the cause of death, showing that they fully appreciated the importance of vital statistics in the study of the causes and prevention of disease. This question is scarcely understood at the present day, and yet, as remarked by Dr. Billings, "when we wish to study the healthfulness of a city, whether it is getting better or worse, or judge correctly the effects of certain sanitary laws, we should not only know the number of deaths, but also the amount and character of the prevalent diseases, together with accurate information as to the number of population at different ages."

The repeated invasion of the Oriental pest appears to have everywhere compelled some sanitary efforts and an imperial decree in 1426 required the appointment of city

physicians throughout Germany, whose duty it was to adopt preventive measures.

A city ordinance of Nürnberg in 1562 gives detailed directions as to the quality of bread, beer and wine offered for sale, the cleaning of streets and houses, the disposition of infected clothing and bedding, the fumigation with sulphur and straw of pest-houses, etc.

In 1685 Prussia established a Central Medical Bureau, and appointments of health officers and privy medical counsellors were made, whose duties consisted in advising the men entrusted with the care of the government on matters relating to public health, and some of these titles are still in vogue in Europe. About the same time sanitary improvements in the way of widening streets for the purpose of supplying more air and light to the habitations, and better methods for the collection and removal of the wastes of human life were introduced, but, broadly speaking, at the close of the 17th century the habits of the people in Europe were generally filthy and in striking contrast to those observed among the most untutored savages of the present day.

In Madrid, we are told, that not even a privy existed in 1760. It was customary to throw the ordure out of the windows at night, and it was removed by scavengers the next day. An ordinance having been issued by the king that every householder should build a privy, the people violently opposed it as an arbitrary proceeding, and the physicians remonstrated against it, alleging that the filth absorbed the unwholesome particles of the air which otherwise would be taken into the human body. His majesty, however, with commendable zeal, persisted, but many of his citizens, in order to keep their food wholesome, erected privies close to their kitchen fireplaces.

With such unsanitary conditions we need be surprised that the mortality in towns was greater than their birth-rate and that the city population had to be recruited continually from the country, conditions which existed until the beginning of the present century. Professor Finklenburg, of Bonn, estimates that the average human life in the 16th century was only 18 to 20 years, while to-day it is over 40 years.

The mortality of London between 1660 and 1679 was 50 per 1,000 of inhabitants; from 1679 to 1728, including the period of pests, it was 80 per 1,000; between 1728 and 1780 it was still 40 per 1,000, while at the present time it is between 20 and 21 per 1,000, and the mean annual death-rate in England is less than 19 per 1,000. Without underestimating the brilliant achievements of Jenner's discovery of vaccination in 1796, which as a preventive measure has saved millions of lives, no two factors have contributed so much to the general result than the improvement of the air we breathe and the water we drink. Indeed, we have ample evidence that, with the introduction of sewers and public water supplies, the general mortality in numerous cities, during the past forty years, has been reduced fully one-half, the good effects being especially shown by a marked decrease in the number of cases of typhoid fever, diarrhœal diseases and consumption. The vital statistics of Great Britain furnish the proof. The mortality of Salisbury within the last 30 years has been reduced from 40 to 16 per 1,000; at Dover from 28 to 14 per 1,000; at Rugby from 24 to 10 per 1,000; at Croydon from 28 to 15 per 1,000 and at Matlock from 18 to 9 per 1,000.

Now let us see what a pure water supply has accomplished. A summary of the evidence on this subject reveals the significant fact that cities, both at home and abroad, in which there has been the most marked decrease in the typhoid-fever death-rate, are those in which a pure supply has been substituted for a pre-existing contaminated one. Thus, for example, the typhoid-fever death-rate in Boston in 1846–1849 was still 17.4 per 10,000; in 1890–1892 it had fallen to 3.2 per 10,000, the city having in the meantime expended $25,000,000 on its water supply. The rate from this disease in Lawrence, Mass., for five years prior to 1893 was 12.7 per 10,000. After the establishment of sand filters, in September, 1893, the rate fell during the first twelve months to 5.2 per 10,000. In other words, 48 human lives at a value of $5,000 each, or a total value of $220,000, were saved to that city by an expenditure of only $65,000 for the plant and $4,000 running expenses per year. The typhoid-fever death-rate in Chicago in 1892 was 14.3 per 10,000. After improving the water supply it fell to 5.6 per 10,000. In 1874 the rate in Vienna was 11.5 per 10,000, and, with the introduction of a pure water supply, it has fallen to less than 2 per 10,000. The experience of London, Berlin, Munich and a host of other cities has been precisely the same.

Munich was notorious for its excessive typhoid-fever death-rate, it being 29 per 10,000 in 1856. With the introduction of a pure water supply and improved sewer system it has fallen to less than 2 per 10,000.

The question has passed beyond the speculative or experimental stage. Conservative cities are not in the habit of authorizing the expenditure of large sums of money without counting the cost and results; and the mortality statistics have furnished more eloquent and conclusive arguments than the most zealous advocates of sanitary reforms.

An abundance of water does not limit the spread of typhoid fever, for New York City, with only 78 gallons per head a day, has only 2.3 deaths; while this city, with a daily per capita consumption of 173 gallons, furnishes 8.12 deaths, and stands to-day No. 7 on the list of 54 American cities as regards an excessive death-rate from typhoid fever, only Denver, Allegheny, Camden, Pittsburg, Newark and Charleston furnish a higher rate.

Let us advocate, therefore, an ample quantity of pure water, and until this is accomplished let us filter and boil our drinking water, boil our milk, and thoroughly disinfect the excreta of typhoid-fever patients. The present century can boast therefore, of many advances in hygiene, particularly since the European invasion of cholera in 1830. The English towns and cities which had been visited by this disease and those fearing similar scourges were perfectly willing to profit by the investigations of the causes of infectious diseases and freely instituted sanitary reforms in the establishment of sewers, public water supplies, sanitary homes, etc. The example of England was followed by all civilized nations, with similar results. The effects of sanitation, as taught by Dr. Parkes, were demonstrated during the Crimean War and, as beautifully expressed by Virchow during our Civil War, reached 'the highest point in humane efforts ever attained in a great war.'

A study of the causes of infectious diseases also suggested more enlightened means for their prevention or mitigation, as the compulsory vaccination against small-pox, compulsory isolation and disin-

fection in a number of infectious diseases, the prevention of soil and water pollution for the restriction of typhoid fever, cholera, dysentery and other water-borne diseases, and, finally, the labors of Pasteur, Koch, and Sternberg of our country, in the identification and destruction of disease germs, have accomplished a great deal and opened a field of preventive inoculations which promises other practical results. The medical profession speaks of preventable diseases, and the Prince of Wales, in his opening address at the International Congress of Hygiene, held in London in 1891, very properly said: "If certain diseases are preventable, why are they not prevented?" The facts are that whilst the scientific physician knows fully well that if, for example, the dejecta of every typhoid-fever patient were promptly disinfected with germicides, typhoid fever would be stamped out in the course of a few years, he is not in a position to enforce this opinion by effective laws.

To illustrate what germicides and antiseptic methods have accomplished, let me remind you that the mortality from all amputations in the Crimean War (1854–55) was 63.5 per cent., in our Civil War it was still 48.7 per cent., but this percentage has steadily fallen until, in 1890, it was only 6.9 per cent. A century ago the mortality from puerperal fever at the lying-in department of the Hotel Dieu in Paris amounted to 10%. Semmelweis, in 1847, first insisted upon compulsory antiseptic midwifery, and since that time the mortality has fallen in all well-regulated maternities to less than one per cent. Witness, also, the advances made in the construction of model hospitals, asylums, schools, prisons and industrial establishments in relation to light, heating, ventilation, etc.

At the close of the last century the mortality among the inmates of French prisons was 250 *pro mille;* in the German prisons, in the forties, it was between 34 and 60 per 1,000, while in 1878 to 1882 it had fallen to 27 per 1,000.

In the matter of personal hygiene much has been done in the way of improved dietetics, clothing, exercise, and especially in the care and feeding of infants, but much remains to be done.

I will not weary you with a recital of what other countries have accomplished in the way of national and local health boards, enactment of health laws, the enforcement of sanitary police regulations, laws for the suppression of quackery and quack remedies, all of which have contributed greatly to the sum-total in the field of public sanitation.

While the people of the United States were not slow in adopting and originating sanitary measures of great value, our ideas of personal liberty, guaranteed to us by the Constitution, evidently prevented early legislation in matters of public health, except in matters of State quarantine, for fear that such legislation might affect the personal habits of the citizen and lessen his freedom of action. At all events, the first State Board of Health was established in Massachusetts only in 1869, since which time nearly all of the other States have followed her example. In 1872 the American Public Health Association was organized, and numbering, as it does, among its members some of the best minds in the profession, much good has been accomplished by this body and the so-called 'sanitary conventions' in molding public opinion and in framing and recommending health laws.

Measures for the control and restriction of contagious diseases have been adopted by most of the Health Boards, and a number of States enforce compulsory vaccination for school children, and have passed laws regulating the sale of poisons, and for the prevention of food and drug adulterations, and the extermination of bovine tubercu-

losis. In 1879 Congress created a National Board of Health, whose duty it was to make investigations into the causes and means of prevention of contagious and infectious diseases, to indicate measures of national importance and to be a center of information for all matters relating to public health. For want of appropriation this important body has ceased to exist, and since 1883 the duties relating to international and interstate quarantine have been discharged by the Surgeon-General of the Marine Hospital Service; his bureau, apart from the management of hospitals and stations for the care of sick and disabled seamen of the merchant marine, has also undertaken the collection and dissemination of mortality statistics and sanitary information, scientific investigation into the causes of disease, the physical examination of immigrants under the law excluding those affected with contagious disease—service in the office of consuls at foreign ports to assure the accuracy of bills of health—and other miscellaneous duties. Since Congress has failed to act upon the President's repeated recommendation and the petition of numerous medical societies for the creation of a National Health establishment, there is no good reason why the scope of duties and powers exercised by the Marine Hospital Service should not be enlarged.

An advisory board, composed of one representative from the various State Boards of Health, the chiefs of the medical department of the army and navy, and of the Bureau of Animal Industry, Census and Weather Bureau, and one of the legal officers of the government, could meet once or twice a year and decide upon a line of work for the promotion of public health.

One of the most pressing needs is an investigation into the pollution of water-supplies when such pollution affects or threatens to affect the sanitary condition of the people of more than one State, because the individual States are powerless to protect themselves against the misdeeds of their neighbors. Mr. Barthold's bill for the appointment of a River Pollution Commission, two years ago, was defeated; yet that same Congress appropriated $40,000 for the extermination of the Gipsy moth. England enjoyed the benefit of such a commission as early as 1855, and, in order to prevent, remedy and remove the danger of polluted water-supplies, adopted a comprehensive system for the disposal of sewage and of water filtration, the fruits of which have already been referred to.

We know that the Potomac River receives the drainage from every town and hamlet washed by its shores and tributaries, and what is true of the Potomac is equally true of the Ohio, Mississippi, Merrimac, Connecticut, Missouri, the Red River, the Columbia and Wabash Rivers, which are the sewers and, at the same time, the source of water supply for nearly all the cities located upon its banks, and these cities, as shown by the statistics collected by the Marine Hospital Service, show moreover a marked prevalence of typhoid fever, confirming what has elsewhere been proved, that this disease, as also cholera, dysentery and diarrhœal diseases, can be carried from one town or city to another by means of a water course.

Surgeon-General Wyman in a recent contribution estimates, from statistics received in his office, that every year there are no fewer than 45,000 deaths caused by typhoid fever alone throughout the United States, and, based upon an estimated mortality of 10%, it is within reason to assume a yearly prevalence of 450,000 cases of this disease. The average duration of a case of typhoid fever is not less than 30 days. If we calculate that an average of $1.00 is expended per day for care, treatment and loss of work, and that the value of a human life is $5,000 each, we have a total loss in

the United States of $238,500,000 per annum from one of the so-called preventable diseases. Reduce the prevalence of this single disease one-half, which has been accomplished in England, and the oft-recurring question: "How is it our fathers got along without these so-called modern improvements?" will be satisfactorily answered from an economic point of view.

Another subject which deserves special attention is the question of pure foods and drugs. It would lead me entirely too far even to touch upon all the gross frauds and their serious consequences which are daily perpetrated, but permit me to refer to a very universal article of food, viz., milk. Analyses of milk sold in New York City showed an average dilution with 33% of water, the fraud amounting to $10,000 per day. The State Inspector found 12% of water added and 20% of cream removed. The results in St. Louis, Chicago and this and every other city are similar, and indicate the desirability of stringent laws governing the milk traffic as a protection to the pocket of the consumer; but when we remember that Dr. Busey and the writer have collected and tabulated 138 epidemics of typhoid fever, 74 of scarlet fever and 28 epidemics of diphtheria, and that an analysis of the evidence showed that the poison of these diseases may reach the milk by soakage of the germs into the well water with which the utensils are washed, or by the intentional dilution with infected water; that the infection can be conveyed by animals wading in sewage-polluted water, or by the dairy employes acting as nurses, or suffering themselves from some mild infection while continuing their usual duties, or are convalescent from the disease; and that infection has taken place through the agency of scrubbing brushes, flies and other insects, exposure of the milk in or near to the sick rooms, or washing the patients with the same cloth used in wiping the dairy utensils, we see at once that dairies should be under sanitary control to prevent the propagation of disease by infected milk. This should include inspection of the dairy stock by competent veterinarians, so that the milk of animals suffering from bovine tuberculosis, erysipelas, anthrax, pleuro-pneumonia, foot and mouth disease, septic and other fevers, specific enteritis, rabies, tetanus, garget and other inflammatory conditions of the teats and udder may be excluded from the supply. Milk may also be rendered unfit for use by reason of improper food and care of the animal, or while the animal is being treated with powerful remedial agents. It is interesting to note that of the 240 milk epidemics collected by us, 187 were reported by English, 31 by American and 9 by Scandinavian observers; 8 came from German, 3 from Australian, and 1 each from French and Swiss sources. And right here it is suggested that the infrequency of milk-typhoid in France and Germany is due to the fact that milk is rarely used in its raw state on the Continent of Europe, and the germs are destroyed by sterilization.

The first movement towards securing comprehensive legislation against the adulteration of foods and drugs in this country was made in 1879. This is all the more surprising because Dr. Mann in his Medical Sketches of 1812 remarks that "the bread on the Niagara was made of damaged flour, such as was either not nutritious or absolutely deleterious." It was believed also that the flour contained in some instances an earthy substance, and that this adulterating substance was 'plaster of paris.' Again, during the Civil War, as early as in the winter of 1861–62, an extract of coffee furnished the troops in the vicinity of Alexandria produced nausea and vomiting in those who used it, and subsequently a government contractor, for having practiced

food adulterations, was sentenced to a protracted imprisonment.

Instances, therefore, were not wanting pointing to the necessity of such laws; nevertheless, it was not until 1881 that three States, New Jersey, New York and Michigan, passed laws to prevent the adulteration of food and drugs. The law in New York commenced in the summer of 1882. At the close of the year 286 samples of food and drugs had been submitted to the public analysist for examination, of which 194 had been reported upon. Of 119 samples of food, 50 were found adulterated; while of 75 samples of drugs, 32 were adulterated.

Since 1883 quite a number of States have enacted similar laws, but I regret to say that in spite of the absolute necessity for such a law in this city, as revealed by the report of the chemist of the Health Office, the bill introduced during the last session of Congress failed to become a law. The majority of States have enacted laws to regulate the sale of poisons, but a careful study shows that they should be amended and greater restriction placed on the sale of poisons generally. A recent investigation, by a committee of the Medical and Surgical Society, into the extent of the opium habit in the District of Columbia, reveals the fact that during the past 10 years 7 persons died from the opium habit, 36 persons died from accidental or negligent opium poisoning, and 125 cases of opium poisoning and 70 patients were treated for the opium habit in our public hospitals. This does not include persons treated for acute or chronic opium poisoning in private practice. Investigation into the causes of the opium habit led to the conclusion that one class of subjects have contracted the habit by the use of the milder preparations of opium, and some of the various proprietary or secret remedies commonly employed as domestic remedies, such as paregoric, McMunn's elixir, diarrhœa mixtures, pain-killers, etc. Another class have evidently acquired the habit by the constant use of prescriptions containing opium or its preparations for the relief of pain, the individuals being at first quite unconscious of the enslaving nature of the drug. Still another class of persons belong to the moral degenerates of fast men and women, who have acquired the habit by contact with opium habitués including opium smokers, and through solicitation, invitation and persuasion have fallen victims to the vice.

Since the opium habit is often established by the unauthorized and indiscriminate renewal of prescriptions containing opiates, the New York Legislature very wisely enacted, in 1886, a law that no pharmacists shall refill more than once prescriptions containing opium or morphine, or preparations of either, in which the dose of opium shall exceed $\frac{1}{4}$ grain, or morphine $\frac{1}{20}$ grain, except with the verbal or written order of a physician. A similar bill was introduced into Congress during the winter session, but failed to become a law. This city is also without a law for the suppression of the opium joints, in spite of the fact that a man died a few months ago from the effects of opium smoking in one of the joints, of which there are two; and a conservative estimate places the number of habitual opium smokers in the city between 150 and 200.

It is clearly the duty of the State to close opium dens and restrict the sale of poisons, and in regard to the sale of patent and proprietary medicines containing poisonous drugs the contents should be expressed on the label and the word poison added.

At the risk of taxing your patience, permit me to refer to the subject of patent and proprietary medicines.

By the term patent medicine, as properly employed in this country, England and Europe generally, it must be understood

that the composition is known and can be seen at the Patent Office. The proprietary medicine is a secret preparation protected by a trade mark in this country, and hence preferred by the owner, but both are vaguely termed by the public patent medicines.

The extent of the traffic will be apparent when I tell you that up to December 31, 1896, the United States Patent Office had issued patents on the following:

Disinfectants	235
Extracts	226
Hair dyes and tonics	43
Insecticides	145
Internal remedies	356
Plasters	48
Topical remedies	351
Veterinary remedies	75
TRADE MARKS.	
Drugs and chemicals	614
Medical compounds	4979

The proprietary medicines are subect to the control of the State authorities, and if containing alcohol in sufficient quantity to be intoxicants are subject to Internal Revenue Laws, but so far as my knowledge extends little or nothing has been done in this country and in England to control the sale of secret remedies. Dr. G. Danford Thomas, Coroner of London and Middlesex, before the International Congress of Hygiene in 1891, very justly urged that all proprietary medicines should be under the Patent Laws, because the composition is at least disclosed; he would abolish licences to sell them and confine the sale to chemists and druggists only. In these matters we could certainly profit by the example of the Japanese, Italian, French and German laws. The Japanese government has established a public laboratory for the analysis of chemicals and patent medicines. The proprietors are bound to supply a sample with the names and proportions of the ingredients, directions for its use and an explanation of the supposed efficacy. During the year 1889 there were no fewer than 11,904 applicants for licenses to prepare and sell 148,091 patent and secret medicines. Permission for the sale of 58,638 different kinds was granted; 8,592 were prohibited; 9,918 were ordered to be discountenanced, and 70,943 remained still to be reported on. The majority of those authorized to be sold were of no efficacy, and but few were really remedial agents. The sale of these was not prohibited, as they were not dangerous to the health of the people. No objection can be urged to this law from a sanitary point of view, except that it continues to protect the 'pseudo-scientist.'

In Italy (which country, by the way, has the best national board of health) the sale of secret remedies in January, 1891, became subject to the following regulations: The composition as to the quality and quantity of the active substances contained must be written on the labels and on the advertisements; no special therapeutic virtue or indication shall be attributed to them either on the label or advertisement; they shall be sold only by chemists under the vigilance of the sanitary authorities and with medical prescriptions.

In France the pharmacier is forbidden to sell secret remedies or even to keep them on his premises under heavy penalties.

In Germany the chemist may sell patent medicines when ordered by the prescription of the physician. He must not sell secret remedies. All patent medicines sold by the chemist must be prepared under special supervision and according to the rules of the pharmacopœa.

From the foregoing we may conclude that, while a good deal has been accomplished by public and private sanitation, much remains to be done before the average length of human life reaches threescore and ten.

GEORGE M. KOBER.

GEORGETOWN UNIVERSITY.

CONTRIBUTIONS TO OUR KNOWLEDGE OF MICRO-ORGANISMS AND STERILIZING PROCESSES IN THE CANNING INDUSTRIES.

In a paper read before the Society of Arts in October, 1896,* we showed the extent of the canning industry in this country, and the importance to it of accurate knowledge of the bacteriological principles of sterilization. In that paper we dealt with the packing of clams and lobsters, and described some of the bacteria which are active in the deterioration of these products in case sterilization is not complete. It is interesting to notice that some of the results which we published at that time have lately been confirmed by a specialist employed by the Canadian government† to investigate the discoloration of canned lobsters.

We now desire to put on record a preliminary account of our more recent investigations in another branch of the industry, viz., the packing of sweet corn. This art constitutes a very large industry, as is shown by the fact that in 1895 72,000,000 two-pound cans (72,000 tons) were packed in the United States. The growth of the business has been rapid, for it was not until about 1853 that corn was packed at all with success.

Sweet corn, when properly prepared, is one of the most valuable of all canned foods, as it retains much of its original flavor, is popular, and is sold at a price within the reach of all. If, however, the sterilizing has not been thoroughly done there may result fermentations caused by bacteria which have not been killed, producing what is known as 'sour' corn.

Our investigations commenced in February, 1897, with the examination of a large number of cans of sour corn. On opening the cans no change was noticeable to the eye, the corn appearing fresh and of a natural color. In some cases a sour odor could be detected, but in others this was not observed. It was to the taste that the trouble was most apparent, the corn being sour and of a peculiar, astringent flavor. Bacteriological examinations showed sound cans to be sterile, while spoiled cans invariably gave evidence of bacterial action. Pure cultures of six species were obtained, of which five were bacilli, and one was a micrococcus. By inoculating sterile cans of corn with these organisms we have been able to produce souring in all respects similar to that of the spoiled cans from which they were originally taken.

In order to study these fermentations more thoroughly and to ascertain, if possible, the source of the bacteria causing them, we spent nearly the whole of the corn-packing season of 1897 at an establishment in Oxford county, Maine, where every convenience for scientific study of the process was put at our disposal by the proprietors. We were thus enabled to thoroughly investigate the methods of procedure from the harvesting of the green corn to its ultimate shipment in cans. It is very necessary that the utmost cleanliness and dispatch should be observed in all the operations, so that the chances of infection from bacteria may be reduced to a minimum. In this factory the strictest caution was exercised in these respects, everything being kept scrupulously clean.

The corn is generally picked in the morning, and is delivered to the cannery as early as possible. One or two men make it their special duty to visit the farms once or twice a week during the season to keep informed as to the condition of the crop and to 'order in' the corn as it becomes sufficiently matured. As the ears are delivered at the factory they are arranged in low piles on the ground in an open shed to protect them from the sun. The husks and the silk are

* Technology Quarterly, Vol. X., No. 1.

† Supplement No. 2, 29th Annual Rep't, Department of Marine and Fisheries, Ottawa, 1897.

taken off by hand, and the corn is then quickly carried to the cutting machines, in which, by a series of knives and scrapers, the kernels are quickly and cleanly separated from the cob. Any stray bits of cob or silk which may be mixed with the corn are now taken out as it passes through the 'silker,' a machine arranged somewhat on the plan of a gravel-sifter, that is, with two cylindrical wire screens one inside the other, placed on an incline and rotating in opposite directions. The corn drops through the meshes of the screens, while the refuse passes out at the lower (open) end.

The corn is now weighed, mixed with water in the proper proportions, and is then ready for the 'cooker.' There are several varieties of these machines in use, all of which are alike in principle but differ somewhat in details of construction. Their object is to heat the corn evenly and quickly to a temperature of 82–88° C. (180–190°F.) and to deliver it automatically into the cans. A single machine fills about thirty cans a minute. After having been wiped, the cans are capped, soldered and tested for leaks. Sterilization, the final and most important step in the whole process, now follows, this being done in retorts, by steam under pressure. The length of heating, or 'processing,' and the pressure which is given vary somewhat in different factories.

As we have shown in our previous paper, in order to insure sterilization in practice, it is necessary to obtain and maintain a temperature in excess of 100° C. (212° F.) throughout the contents of the can. Intermittent sterilization may be employed, but is less efficient and is not practicable upon a large or commercial scale. We have found by experiment that sixty minutes at 121° C. (250° F.) is sufficient time for sterilizing corn, and it seems probable that this can be shortened somewhat or the temperature reduced. Further experiments are in progress to decide this question.

Through a demand that canned corn shall be very light in color there has been, apparently, a pressure put upon the packer to shorten the time of heating or to reduce the temperature in his retorts. The large losses which have resulted in recent years from sour corn have been due principally to this demand. By the use of registering thermometers we have proved that corn is a very poor conductor of heat, and that the time necessary to bring all portions of the center of the cans to the requisite temperature is a factor whose importance cannot be overestimated. We have proved by experiment that, with 13 pounds of steam in the retort, the corresponding temperature of which is 118.8° C. (246° F.), it requires 55 minutes for the same temperature to be registered at the center of a can placed in the middle of a retortful of corn. With the same pressure and under the same conditions at the end of 45 minutes a temperature of 114° C. (237.2° F.) was reached, and at the end of 30 minutes 108.3° C. (227° F.). Thus it is evident that with the present methods any reduction of time of heating is attended by considerable risk. If any means could be devised by which the heat would more quickly reach the center of the cans it might be safe to shorten the time of heating. There is a prospect that before long some such modifications may be possible.

We have made a careful bacteriological study of all the different steps in the process and of the corn as it comes from the field, and have found upon the corn in the field bacteria which appear to be identical with those isolated from cans of sour corn. Repeated tests of corn from the cob showed the presence of bacteria. Corn which had passed through the cooker, and cans of corn which had been 'retorted' for 30 minutes or less, also contained the same species of bacteria as were found upon the raw corn.

All these bacteria liquify gelatin, and

grow very rapidly, as is proved by the fact that streak cultures showed well marked growth four hours after inoculation. Detailed descriptions of the organisms and of many more experiments will be given in our full paper on this subject to appear in a forthcoming number of the *Technology Quarterly.*

Boston, November 12, 1897.

AMERICAN ORNITHOLOGISTS' UNION.

The Fifteenth Congress of the American Ornithologists' Union convened in New York City, Monday evening, November 8th. The public sessions, lasting three days, were held in the library of the American Museum of Natural History.

William Brewster, of Cambridge, Mass., was re-elected President; Dr. C. Hart Merriam and Robert Ridgway, of Washington, D. C., Vice Presidents; John H. Sage, of Portland, Conn., Secretary; William Dutcher, of New York City, Treasurer; Charles F. Batchelder, Frank M. Chapman, Chas. B. Cory, Ruthven Deane, Drs. Jonathan Dwight, Jr., A. K. Fisher and L. Stejneger, members of the Council. By a provision of the by-laws, the ex-Presidents of the Union, Dr. J. A. Allen, Dr. Elliott Coues, and Mr. D. G. Elliot, are *ex officio* members of the Council.

One active and eighty-eight associate members were elected. As a direct result of the Audubon Society movement, creating a popular interest in the study of birds, more women than usual were elected to associate membership.

An address in commemoration of Major Charles Emil Bendire, U. S. A., a distinguished member of the Union who died during the past year, was prepared by Dr. J. C. Merrill, U. S. A., and presented by Mr. Elliot. Major Bendire was a well-known oologist, and will always be remembered by his invaluable 'Life Histories of North American Birds.'

Dr. Coues exhibited the portfolio carried by John James Audubon in Europe and America, and also the original MS. of the first volume of his 'Ornithological Biography.' Some original bird-drawings by John Woodhouse Audubon were also shown.

Mr. Abbott H. Thayer, the eminent portrait painter, gave an out-of-door demonstration of the underlying principle of protective coloration, in continuation of his remarks on the subject at the previous meeting. Mr. Thayer showed a pair of decoys with the belly part cut off, so that in lying on the cut-off side they represented crouching birds or mammals. He then repeated upon them the coloring which he had exhibited at Cambridge upon entire decoys (decoys poised a few inches above the ground). This, he said, was to more clearly illustrate what he stated in his first paper on protective coloration, namely, that the normal gradation of sky's lighting is effaced *by the color gradation of the animal at every point*, the median dorsal line having the darkest markings, so that the gradation toward the white of the belly *begins close to this dorsal line.* Mr. Thayer placed the two decoys side by side on a plank, and covered one of them uniformly with the same dry earth which he spread about it on the plank, so that all of its visible surface and that of the plank on which it lay were absolutely of one tint—monochrome; yet it was conspicuously visible at a long distance, because of its normal gradation of shading from the sky's light, although there was no underside visible to show a culmination of shadow. The other decoy he painted in imitation of a hare's or snipe's gradation and so successfully that it became totally invisible at a distance of four or five yards. He explained that the statement in his first paper

that not a feather of the upper surfaces of the woodcock and grouse had been artificially colored referred only to the feathers along the median dorsal region.

The skin of a cottontail rabbit was exhibited, showing a most perfect gradation from the black hairs of the middle of the back and over the shoulders to the white of the belly.

This communication, in connection with that given at Cambridge a year ago, completes Mr. Thayer's admirable demonstration of his theory of the great underlying principle of protective coloration in animals.

On Wednesday evening, November 10th, an illustrated lecture entitled 'A Naturalist's Expedition to East Africa,' was given in the large lecture hall of the Museum by Mr. D. G. Elliot before an audience of some 1,500 persons.

Mr. Wm. Dutcher, Chairman of the 'Committee on Protection of North American Birds,' read a most interesting report on the work done during the past year. This report will be published in abstract in *The Auk*, and printed in full as a separate pamphlet.

Mr. Frank M. Chapman gave an exhibition of lantern slides of birds in nature, from material contributed by himself and other members of the Union. This was followed by Professor A. S. Bickmore with colored lantern slides showing recent advances in methods of visual instruction.

Dr. Coues remarked upon certain *Laridæ* which were before him, and Dr. Jonathan Dwight, Jr., showed a specimen of a new species of bird for North America (*Puffinus assimilis*).

An informal talk on the Gyrfalcons was given by Mr. Chapman, who exhibited specimens from Greenland and Labrador. Remarks followed by Dr. W. E. Hughes, who accompanied the first Peary expedition to north Greenland.

Following is a list of the papers read at the sessions, in addition to those already mentioned:

Protective Adaptations of Insects from an Ornithological Point of View: SYLVESTER D. JUDD.

Summer Birds of the West Virginia Spruce Belt: WILLIAM C. RIVES.

Is Uniformity in Local Lists Possible? JONATHAN DWIGHT, JR.

Ten Days among the Birds of Northern New Hampshire: JOHN N. CLARK.

Some Notes on Liberian Birds: HARRY C. OBERHOLSER.

Remarks on a New Theory of the Origin of Bird Migration: J. A. ALLEN.

Experiences of an Ornithologist in Mexico: FRANK M. CHAPMAN.

The Great Roosts on Gabberet Island, Opposite North St. Louis: O. WIDMANN.

The Terns of Gull Island, N. Y.: J. HARRIS REED.

The Petrels of Southern California: A. W. ANTHONY.

The Terns of Muskeget Island, Mass.: GEORGE H. MACKAY.

The Northern Raven Breeding in New England: H. K. JOB.

The Summer Birds of the Catskill Mountains, with remarks upon the Faunæ of the Region: EDWIN I. HAINES.

Breeding Habits of the Common Robin in Eastern Massachusetts: REGINALD WEBER HOWE, JR.

The next meeting of the Union will be held in Washington, D. C., commencing November 14, 1898. JNO. H. SAGE,
Secretary.

CURRENT NOTES ON ANTHROPOLOGY.

THE ABORIGINAL ART OF ECUADOR.

THE well known Alpine explorer, Mr. Edward Whymper, during his expedition to the Andes made a considerable ethnographical collection in and near Ecuador, a description of which, with illustrations, is given by Mr. O. M. Dalton in the *Journal* of the Anthropological Institute for August.

The most interesting results refer to the forms of axes and similar stone implements. There are numerous types in Ecuador, many seemingly indigenous, while almost all the Colombian forms 'can easily be traced to a foreign source.' There are frequent instances of resemblance between

types common to the Antilles and Ecuador, and these resemblances are most abundant in the islands most accessible to the South American continent. It is also noted that one quite peculiar form of stone axe, with a depression at the butt and rounded lateral arms, which seems to have reached its perfected development in Ecuador, has been discovered also, both in stone and copper, in tombs of the IVth and XIIth dynasties of Egypt; another illustration of the parallelism of artistic development. The pottery of Ecuador, as shown in the collection, is closely assimilated to that of Chiriqui and other parts of Central America.

THE BERBERS OF MOROCCO.

The most accurate description of this people since that of Quedlinberg is given by Mr. W. B. Harris in the *Journal* of the Anthropological Institute for August. He notes their complexion as nearly always fair, while many are red-haired, red-bearded, and with blue eyes. The Susis, however, south of the Atlas, and claiming to be of unadulterated Berber blood, are copper-colored, with high cheek bones and narrow dark eyes. This would seem to bear out Dr. Collignon's theory of a dark and light Berber type. The Riffians are distinguished by a 'scalp-lock,' which they allow to grow thick and long. It is plaited or twisted, and wound around the head. Mr. Harris does not explain its significance. In the central Atlas they still call themselves 'Berber' (plural Berebber), but the meaning of the term was not obtained.

They apparently have no knowledge of the old Hamitic or modern Tuareg alphabet, and he asserts that no writing in their tongue exists, though it is occasionally written in Arabic characters. Many tracts of the Riff country of the north have never been visited by Europeans, and the Sultan of Morocco exerts a merely nominal control over it. D. G. Brinton.

University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

A contribution to the much discussed subject of the use of alum in foods is given in the last *Journal* of the American Chemical Society, by Professor C. F. Mabery and L. Goldsmith. The authors describe a series of tests as to the influence of varying quantities of alum on the peptic digestion of blood fibrin. In every case the digestive action was retarded by alum, even when present in very small quantity. In order to test the action under actual conditions, two loaves of bread were prepared, one with alum baking powder and the other with a cream-of-tartar-soda powder. Here, again, the peptic digestion was retarded in the case of the bread containing alum. Similar experiments carried out with salicylic acid, boric acid and with formalin showed that while there was with these antiseptics some retardation of the peptic digestion it was slight in comparison with that when alum was used.

The cause of the rusting of iron which is covered with a protective layer of paint is usually attributed to minute cracks in the paint, occasioned by the unequal expansion of the iron and paint. Edmund Simon gives in *Dingler's Polytechnisches Journal* the results of a study of the conditions of this rusting, and concludes that paint stands changes in temperature, but is always hygroscopic, and when swollen by moisture is pervious both for water and gases. The best way to prevent such rusting is to use three or four coats of a paint, which adheres as closely as possible to the iron, and which contains the largest possible quantity of oil.

In the *Zeitschrift für physikalische Chemie* John Gibson contends that in all cases the chemical action of light is such that the new products have a higher conductivity than the original. This is true in the case of selenium, sulfur, phosphorous and mercuric sulfid, in the combination of hy-

drogen and chlorin, and in the reduction of silver and mercury salts. The action of light on nitric acid seems to be the only exception, but this is only an apparent exception, as the conductivity of nitric acid solution increases up to 32 per cent. when the maximum is reached, whilst the decomposition by light ceases when the concentration has fallen to 47 per cent.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE anniversary meeting of the Royal Society will be held on Tuesday, November 30th, when the officers for the ensuing year will be elected. Lord Lister will be recommended for re-election as President.

THE new house of the American Society of Civil Engineers, 220 West Fifty-seventh street, erected at a cost of $200,000, was formally opened on November 24th. Addresses were made in the new auditorium in the afternoon by the President of the Society, Mr. B. M. Harrod, of New Orleans, and there was a reception in the evening.

THE Danish Geographical Society has awarded its gold medal to Dr. Sven Hedin.

DR. GUIDO SCHNEIDER has been appointed Director of the Biological Institute recently established at Sebastopol.

THE death is announced of Professor Henry Calderwood, since 1868 professor of moral philosophy in the University of Edinburgh, on November 20th, at the age of sixty-seven years. He was the author of numerous publications on education and philosophy, among the more important of which were the 'Relations of Science and Religion' (1881) and the 'Relations of Mind and Brain' (1879), the latter being one of the first systematic treatises on physiological psychology.

THE *Athenæum*, in announcing the death, on November 1st, of the Rev. Peter Bellinger Brodie, of Rowington, in Warwickshire, at the age of 82, states that while a student at Cambridge, Mr. Brodie, like so many others, acquired an enthusiastic love for geology, under the teaching of Professor Sedgwick. His name soon came to be identified with the study of fossil insects, and in 1845 he published a work on this subject. Mr. Brodie was elected a Fellow of the Geological Society as far back as 1834; and the Society recognized the value of his work by the award, in 1887, of the Murchison Medal. A selection from Mr. Brodie's extensive geological collections was acquired a short time ago by the British Museum.

WE regret also to record the following deaths among foreign men of science: Dr. G. H. Otto Vogler, aged seventy-five, a versatile writer on natural history; Dr. Johannes Frentzel, Director of the Biological Station on the Müggelsee, near Berlin, aged 38 years; Dr. L. A. Buchner, professor of pharmacology at Munich, aged eighty-four years; Professor Karl Müller, Director of the Experiment Station for Agricultural Chemistry at Hildesheim, and of Dr. Fr. Stohman, honorary professor of agricultural chemistry at Leipzig, aged sixty-five years.

THE report of the Commissioner of Patents upon the business of the Patent Office for the fiscal year ended June 30, 1897, shows that there were received within that year 43,524 applications for patents, of which 23,994 were granted, including reissues and designs. The number of patents which expired was 12,584. The number of allowed applications which were by operation of law forfeited for non-payment of final fees was 5,034. The total receipts were $1,343,779; the expenditures, approximately, were $1,026,644, leaving a surplus of $317,135. The moneys covered into the Treasury of the United States on account of receipts from fees, etc., in patent cases, from July 4, 1836, in excess of the cost of the management of the Patent Office, amounted to $5,093,614.

Nature states that an instructive fisheries exhibition, arranged to illustrate the fishing industries and the application of science to agriculture, has been opened in the Zoological Museum of the University College, Liverpool. The exhibits are fully described in a guide to the exhibition published by the authorities. There is a series of the food fishes of this district, with the more important food matters of each; also a series of useful and useless fishes

which compete with one another by eating the same food. Another exhibit contains specimens of the shell-fish of the district, showing stages in the life-history and growth, legal and illegal sizes, pearl formations and pearls. A case is devoted to a display of printed matter, photographs, drawings and lantern slides, illustrating the publications, both administrative and scientific, of the Lancashire Sea Fisheries Committee, and other work bearing upon the fisheries of the district. The drawings and sketches include a number made by Professor Herdman in illustration of his joint investigation with Professor Boyce on the diseases of oysters and the connection between the oyster and disease.

THE *Senckenbergische Naturforschende Gesellschaft* at Frankfort celebrated its eightieth anniversary on May 30th, and has now published its *Bericht*, giving an account of the celebration, including the official address by Professor Heinrich Reichenbach, the subject of which was 'A Review of the Progress of Biology during the Past Eighty Years.'

THE seventh International Congress of Navigation will be held at Brussels during July of next year.

THE Walsingham Medal for 1898 is offered at Cambridge University for a monograph or essay giving evidence of original research on any botanical, geological or zoological subject, zoology being understood to include animal morphology and physiology. The competition is open to graduates of the University who are under the standing of M. A. on October 10, 1898, on or before which date the essays are to be sent to Professor Newton, Magdalene College.

THE trustees of the New York Public Library, Astor, Lennox and Tilden Foundations, have announced that the design submitted by Carrere & Hastings for the new library building, to be erected on the site of the Forty-second street reservoir, has been accepted, and the prize in the competition awarded to that firm.

IN addition to the relief map of the State and of the Catskill regions issued by the University of the State of New York, the Regents have authorized one of the Adirondacks and another of Manhattan Island which will show its physical features before they were altered by civilization. The chief interest of this action is, however, in the notice to university institutions that duplicates of these relief maps will be made in quantity and furnished to the schools either for cash or as a part of their apportionment at a comparatively trifling cost, so that many schools can hereafter be provided with these valuable maps. 1,000 copies of the mushroom charts, the publication of which created so great interest that the edition was exhausted almost immediately, have been ordered by the Regents in chart form for wall use. Each institution will be entitled to one free in sheets or mounted on muslin and rollers by paying the cost of such mounting.

THE library of the late Professor Carl Vogt has been purchased by the Senckenbergische Naturforschende Gesellschaft of Frankfurt.

THE Paris *Conservatoire Nationale des Arts et Métiers* announces a series of public and free courses of lectures on the application of science to the arts. These lectures are given in the evenings and continue throughout the winter. The lecturers include M. J. Hirsch, M. J. Violle, M. Marcel Deprès, M. Th. Schloesing and other eminent French men of science.

AT the anniversary meeting of the New York Academy of Medicine, on November 18th, an address was given by Dr. Hermann M. Biggs on 'Sanitary Science, the Medical Profession and the Public.'

A REPORT by M Descubes has been presented to the French Chambers of Deputies recommending the plan of connecting Paris with the sea by a maritime canal, proposed by M. de la Grie. The length of this canal would be 185 km., its width at least 35 m., and its depth 6.20 m. The cost is estimated at about $30,000,000, and M. de la Grie is prepared to organize a company to construct the canal if it is allowed the right to collect tolls for ninety-nine years.

AT a recent meeting of the New York Library Club, Dr. John S. Billings described the method of disinfection of books by formalin vapor. He said, according to the New York *Medical Record*, that in some experiments made recently, at the laboratory of the University of

Pennsylvania, a saucer of formalin, a book which had been infected with the bacteria of diphtheria, another with scarlet fever, and another with erysipelas, were placed under a bell jar. The experiment showed that one cubic centimeter of formalin to three hundred cubic centimeters of space would thoroughly disinfect any book in fifteen minutes.

IT is possible that the beaver will survive longer in Europe than in America. It is said that a few individuals are still to be found on the Elbe, the Rhine and the Danube, and Professor Collett, of Christiania, estimates, according to *Cosmos*, that there are now 100 individuals living in Norway, whereas the number in 1880 was estimated at 60. Professor Collett recommends that government protection be afforded to prevent their extermination.

DR. MAX SCHLOSSER has just issued his *Litteraturbericht* of Anthropology and of the Living and Fossil Mammals for the year 1893—a quarto abstract of 82 pages, in fine type, containing critical notices and digests of all the contributions to these subjects during the year. This abstract is from the *Archiv für Anthropologie*, Band 24, and it is an invaluable aid to zoölogists and paleontologists in all parts of the world, especially because it gives the contents of many papers which are not accessible to readers on this side of the water.

DR. BERGER has published the original Italian text, with comments, of a manuscript discovered by him in the Vatican Library in the hand writing of Michael Angelo. It gives a series of prescriptions and treatments for diseases of the eye which it is supposed he collected in view of his own failing eyesight.

THE last issue of the Masters of Medicine series, published by Mr. Fisher Unwin, London, is 'William Harvey,' by D'Arcy Power.

THE *Atlantic Monthly* promises for next year a series of articles by Mr. John Muir, describing The Great Government Reservations, The Yellowstone Park, The Yosemite Park, and The Sequoia Parks; a series by Dr. T. J. J. See on the 'Origin of the Universe,' and a group of articles on modern psychology and its contributions to education, as also articles by Professor C. S. Sargent on the preservation of the forests and by Professor D. G. Brinton on results of American archæological investigations.

MR. BERNARD QUARITCH, London, offers for sale a complete set of the 'Philosophical Transactions of the Royal Society' for £240. The set includes the 'Philosophical Collections' by Robert Hook, seven numbers complete, published in 1679–1682, during which time the Philosophical Transactions were interrupted, which were intended to supply the gap.

THE Open Court Publishing Company, Chicago, propose issuing a series of life-size portraits of eminent philosophers and men of science, should the advance subscriptions warrant the undertaking. They have prepared a preliminary list of sixty-two philosophers and psychologists and offer this set for $7.50. We trust that this very reasonable price, and the value of the work already done in this direction by the Open Court Publishing Company, will secure a sufficient number of subscriptions to lead them to publish the series, and to follow it as they suggest with series of mathematicians, physicists, biologists, etc.

IT is perhaps worthy of note as indicating tendencies of scientific development that of the thirty-six philosophers given in the series drawn up by the Open Court Publishing Company all are dead except one, whereas a large proportion of the psychologists are now living. The list of psychologists is as follows: Cabanis, Maine de Biran, Beneke, G. E. Müller, E. H. Weber, Fechner, Helmholtz, Hering, Aubert, Mach, Stumpf, Munk, Exner, Wernicke, Steinthal, Brentano, Paul Janet, Ribot, Taine, Fouillée, Binet, Bain, Romanes, C. Lloyd Morgan, Bastian, William James. The omission of Wundt's name from the list is probably through inadvertence. In the English names biology is emphasized at the expense of psychology. The names of Ladd and Hall should be added to give America its fair representation.

THE Smithsonian Institution is about to print, in its *Miscellaneous Contributions*, a work entitled 'List of Recorded Earthquakes on the Pacific Coast, 1769–1897' (illustrated), by Edward S. Holden. The data are derived from a similar list of recorded earthquakes, 1769–1888 (with a very considerable number of additions

and a few corrections), which was issued by the University of California in 1888, and from the annual publications of the Lick Observatory (printed in the *American Journal of Science*, the *Publications* of the Astronomical Society of the Pacific, the *Bulletins* of the United States Geological Survey) since that date. The annual records referred to have been compiled by Messrs. Holden, Keeler and Perrine from observations at Mt. Hamilton, and from miscellaneous reports of earthquake shocks. They have been thoroughly sifted and revised in the present work, which is believed to contain all trustworthy data on the subject of Pacific coast earthquakes since 1769.

IN a monograph entitled 'A revision of the American Lemnaceae occurring north of Mexico,' printed in advance from the Ninth Annual Report of the Missouri Botanical Garden, Mr. C. H. Thompson, in continuation of his studies of ligulate Wolffias, published in the Eighth Report, has now brought together, in concise form and with good keys, a synopsis of the entire Order Lemnaceae, as represented in our flora, each species, in addition to a good description, being represented by excellent figures illustrating its habit and structural details. The paper should stimulate increased study of this interesting group of aquatics, the smallest of flowering plants.

WE understand that subscriptions toward the purchase of the paleontological collections of the late Professor Cope for the Philadelphia Academy of Natural Sciences are far from reaching the needed sum. A recent issue of the Philadelphia *Ledger* contains an editorial urging the importance of securing these collections. It remarks:

"The public spirit of the citizens of this city should not make it possible for the collections to be taken elsewhere, as they embrace many of the specimens on which Professor Cope based his original descriptions, and this type material is simply priceless, since it cannot be duplicated. If through the liberality of those interested in the progress of science the Academy of Natural Sciences be placed in possession of this material, that institution will then have in its museum the type collections of Leidy and Cope, two of the greatest authorities on the monsters of the pre-historic world."

SIMULTANEOUSLY with the starting of the railroad at Buluwayo, says the New York *Tribune*, comes the news of the discovery of coal in large quantities in the immediate neighborhood of the place, the prospectors having been able to ascertain that the coal fields in question cover an immense area, extending, indeed, to the Zambesi river. It is this discovery, destined to play so great a rôle in the commercial and industrial development of the southern portion of the Dark Continent, that has led Cecil Rhodes to decide to continue the railroad without delay to the Zambesi river, which will then be in uninterrupted railroad communication with the Cape. Apart from their commercial importance the coalfields may contain fossils of great scientific interest.

UNIVERSITY AND EDUCATIONAL NEWS.

A NEW University was opened at Jassy, Roumania, on November 2d, addresses being made by the king and by the queen of Roumania.

BY the will of the late Julia Bradford Huntington James a trust fund left by the late Ralph Huntington was released, and it appears that the Massachusetts Institute of Technology and the Boston Museum of Fine Arts will each receive about $100,000.

THE Root Hall of Science and the Benedict Hall of Languages of Hamilton College were dedicated on November 16th. The buildings are both of stone and each cost about $30,000. The Hall of Science is the gift of Mr. Elihu Root, of New York, in memory of his parents, his father having been professor of mathematics in Hamilton College. His brother, Oren Root, now holds the same chair.

ARRANGEMENTS are being made to build a science hall at Ripon College, costing $30,000. Five subscriptions of $2,500 have already been received.

ROCKFELLER HALL, the new recitation building given to Vassar College by Mr. John D. Rockfeller, at the cost of $100,000, was dedicated on November 19th. Dr. G. Stanley

Hall, President of Clark University, gave an address on 'A Few Tendencies in College and University Education.'

THE New York *Evening Post* gives the following summary of the attendance at Yale University for the past four years:

	1894.	1895.	1896.	1897.
Graduate	138	176	227	260
Academic	1,150	1,199	1,237	1,242
Scientific	662	584	553	542
Art	41	46	53	77
Divinity	116	105	104	102
Medical	100	125	138	134
Law	195	224	213	194

The decrease in the scientific school is due to the loss of some eighty students who attended under the old land-grant fund régime. The freshmen academic class is the smallest of the five classes this year, whereas there is an increase in the scientific school of 16 students over last year's class.

A CONVENTION of American women propose to assemble in Washington on December 14th to decide on ways and means of arousing public sentiment in favor of a national university. They intend, it is said, to collect the $250,000 necessary for the erection of an administration building, to form the nucleus of the university, and hope to be able to lay the corner stone on February 22, 1899.

THE vacant professorship of pathology at Cambridge University has been filled by the election of Mr. A. A. Kanthack, M.A., of St. John's College, who has acted as deputy for the late Professor Roy. Professor Kanthack, as we learn from the London *Times*, has had a distinguished career at the University of London, where he has taken with honors the degrees of B.A., Bachelor in Surgery, Bachelor in Medicine, was gold medalist, and proceeded to the degree of M.D. in 1892. He has pursued his studies at University College, Liverpool; St. Bartholomew's Hospital, at the Universities of Berlin and Cambridge. His introduction to Cambridge was in 1891, when he was elected to the John Lucas Walter studentship of the value of £200, open to all students for the purpose of conducting original research in pathology. Before that year he had been lecturer in pathology at St. Bartholomew's Hospital, medical tutor at the Royal Infirmary, Liverpool, and senior demonstrator in pathology at University College, Liverpool. He has devoted many years to original research, and was a member of the Leprosy Commission in India. He is the author of a Manual of Practical Morbid Anatomy and of a Handbook of Practical Bacteriology, and also an extensive and frequent contributor to the journals of physiology and anatomy.

DR. THEODORE DES COUDRES has been promoted to an associate professorship of physics in the University at Göttingen and Dr. Otto Knopf to an associate professorship of astronomy in the University at Jena. Dr. Schmitz-Dumond, of Tarand, has been appointed Director of the Agricultural Experiment Station to be established in Pretoria and Dr. A. Ostroumoff to be professor of zoology in the University of Kasan. Professor Küster, of Göttingen, has been appointed head of the division for analytical, inorganic and physical chemistry in the Chemical Institute of the University at Breslau.

DISCUSSION AND CORRESPONDENCE.

THE MESA ENCANTADA.

TO THE EDITOR OF SCIENCE: I thought that I had said the last word as far as I was concerned upon the subject of the Mesa Encantada, but now that Mr. Hodge's pictures have appeared there is one more word to be said. I never dreamed that he or anybody else would have mistaken the manifestly modern and humanly constructed *cairn* which he figures, and about which so much noise has been made, for the *cairn-like* object of which I spoke. The latter is a very different object, and its location gave it some significance, while the former has none of any importance.

The cairn he figures was certainly built by a human being on the 23d of July, 1897, and not by ghosts.

WILLIAM LIBBEY.

PRINCETON, N. J., November 16, 1897.

OBSERVATIONS ON 'THE PRINCIPLE OF IDENTITY.'

THE principle that a thing or relation is identical with itself has given no end of trouble in

discussions respecting experience and knowledge. More than often it has been regarded as an abstract form of self-evident apprehension, whose chief, and perhaps sole, function is to mark the limits of reasoning. How it may have come into our experience has been humorously and seriously debated from Locke downward. It may not be an exact source of knowledge, but this negation does not exclude the peculiar significance attached to *experiencing* the relation in question. The two cases following indicate that there is some meaning to the 'principle' when found in conscious processes at an earlier time.

A bright child, Helen B., four years of age, whose development has been normal in all particulars, perplexed her mother and myself by adding to a conversation, in which she was taking no part and which had no apparent concern for her, these words: "Whatever is alike is the same. If you are good, you have to be good; if you are bad, you have to be bad. Whatever is alike is the same." Tactful questioning failed to bring out any evidence that the utterance was an echo from something the child may have heard. The meaning of the statement seemed to be clear to the child, though able to explain or expand it in no other way. She persisted in the assertion with considerable show of feeling, amounting almost to triumph.

Another and more recent instance is that of a boy in his sixteenth year. In a certain class the teacher was endeavoring to get another pupil to complete the sentence, "A dog is—," for purposes of illustration. After several examples and some hesitation on the part of the second pupil, the first jestingly ventured to supply 'a dog,' the sentence then reading: "A dog is a dog." The teacher accepted the suggestion as 'all right,' and showed how such statements could be made. The boy, however, was confused with astonishment upon learning that his suggestion had passed from jest to earnest, and required a rather long period of time to recover and adapt himself to this relation, which had apparently never occurred to him previously.

These rather opposite cases go to show that the 'principle' is not utterly void when it first arises in the conscious processes, however thoroughly one may claim it to have been operative in primitive mental activities.

EDWARD F. BUCHNER.

NEW YORK.

SCIENTIFIC LITERATURE.

A Popular Treatise on the Physiology of Plants for the Use of Gardeners, or for Students of Horticulture and Agriculture. By DR. PAUL SORAUER. Translated by F. E. WEISS. London and New York, Longmans, Green & Co. 1895.

One of the excellent features of this book is that there has been a consistent endeavor on the part of author and translator to make it a book clearly within the grasp of the persons for whom it is intended.

The author has succeeded in dealing with many of the problems of nutrition, diffusion, assimilation, etc., in a way that is not only attractive, but can be understood by one who has had little previous training in the study of plants.

After the introduction the author takes up first the structure of the root, and in connection with the structure discusses also the function of the root in the processes of absorption and conduction of nutrient materials. This is followed by a chapter on the nutrition of the root, dealing with the substances in the soil which act as plant food, the effect they have on the plant and the form in which they are taken up by the plant. Practical suggestions are made concerning the best treatment of the soil, the nutrition of pot plants, etc. The treatment of roots in transplanting, in repotting, is also considered.

The structure of the stem and leaf are treated in the same readable way in relation to the functions which they play in the general plant economy. The remaining chapters are devoted to plain directions for pruning, propagating, watering and the general nurture of the plant and seed, from the standpoint of the horticulturist and gardener, and this part of the book, at least to one who deals more with the principles of plant development than with horticultural practice, seems to be admirably done.

GEORGE F. ATKINSON.

Contributions to the Analysis of the Sensations. By ERNST MACH. Translated by C. M. WILLIAMS. Chicago. 1897.

The English-reading public is not a little indebted to the Open Court Company for its rendering into English of some of the best foreign writers of our day. Mr. Williams's careful translation of Mach's 'Analysis of Sensations' is a particularly valuable contribution.

In turning again to a work that has been before the public some twelve years, it will be unnecessary to take up anew the discussion of the particular problems treated. The part played by movement, either actually performed or merely 'willed,' in our perception of space (p. 60, etc.), by the mechanism of attention with its background of continuous bodily processes in our sense of time (p. 111, etc.)—the parts played by these factors have come to be well recognized items in our psychological stock-in-trade. Mach's contributions to the subject remain historically interesting as early, clear and richly illustrated efforts to call attention to these elements in our concepts of space and time. His attempt to reconstruct the psychology of tone, if it has not met with any such general acceptance, presents, nevertheless, a method of treatment that no tone-psychology can afford to pass over without notice. Since the fundamental concepts involved go beyond the special field of audition and serve to illustrate an attitude toward the whole psychology of sensation, reference to them may be left for that connection.

The present review may thus confine itself to a discussion of the points of broader interest for which Mach stands. Such a task in connection with the work before us is rendered pleasant by the author's simplicity of style and limpid clearness of thought. It is rendered difficult, on the other hand, by the desultory plan of treatment that he has consciously adopted. For although we are assured in the original preface that the same problem has been kept in mind throughout, yet to justify such a statement one must consider the problem to be a very general one, indeed.

Mach paves the way to the more technical part of his discussion by sketching in a most skillful manner a view of science in general, of psychology as a particular science, of the problem of sensation as illuminated by these general considerations. It is this part of the discussion that appears to the reviewer to be the central interest of the work. One feels, too, that it lay nearest the heart of the author. It seems, then, to demand rather close attention.

Having swept the decks of such 'metaphysical' concepts as 'things-in-themselves,' science starts with complexes of experience, partly permanent, partly changing (p. 2). Among the relatively permanent complexes are the 'self' and the various groups we call bodies. Their permanence is, however, only relative; the division between them not fixed. The changes to which they are subject furnish an instigation to that analysis by which they are disintegrated into 'elements' (p. 5). These elements, for economic purposes grouped together under single names, separated into not very definite wholes, are, in the end, all alike 'sensations' (pp. 10, 152). Thus 'the world consists only of our sensations' (p. 10).

Starting from this empirical 'monistic' standpoint, it is with the 'connections' of this small number of ultimate elements that science deals (p. 18). The fields of the various sciences are defined, not by the kinds of elements they consider, but by the kinds of connections they take into account. Thus, the ordinary division between mind and body and the separation of sciences dealing with each is, like any other distinction between particular sciences, purely a practical device. "That traditional gulf between the physical and psychical research, accordingly, exists only for the habitual stereotyped method of observation" (p. 14). "There is no rift between the psychical and the physical, no *within* and *without*, no *sensation* to which an outward, different *thing* corresponds. There is but *one kind of elements*, out of which the supposititious within and without is formed—elements that are themselves within and without according to the light in which, for the time being, they are viewed" (p. 151). The same elements, viewed as connected in those groups that we call physical bodies, are objects of study for physics; when one of these physical bodies is regarded as an organism their connection is studied by physiology; when considered as a chain of mental events they offer the subject-matter for psychology (p. 153). Thus, all science is primarily an attempt to reproduce facts in

thought. All that it seems to be more than a detailed account of facts arises from the necessity of performing its function in an economical, even though symbolical, way (p. 154).

The empirical, phenomenalistic standpoint above defined is, perhaps, as satisfactory a basis for scientific development as can at present be formulated. It would, of course, be hasty to regard it as a final formulation. That it contains inherent difficulties must have been as evident to the author as it is to the critic. For example, when it is said 'the world consists only of our sensations' one naturally wonders where the frequently mentioned 'connections' between sensations are to come in. Or, again (the historical stumbling block of 'monism'), what is this experiential, or phenomenal, or sensational character, which, if everything possess it in common, would seem to be as difficult to define as a scholastic 'summum genus'? Finally that 'self' which is a group of sensations, an object of experience, conveniently separated on the basis of certain peculiarities it may possess from other objects, is left in undefined relation to that subject or observer by whom and for whose 'economic' ends the separation is made. Again the historic difficulties surrounding the relation of the self as subject to the self as object!

Nevertheless, it is not probable that any other theory removes these difficulties, although many seem more profoundly conscious of their existence. Their clearness and practicability have made views similar to those of Mach, favorite among scientists (cf. Münsterberg, Karl Pearson, *et al.*). Doubtless more elaborate care expended on the foundation would be out of proportion to the strength of the present scientific superstructure that rests upon it.

From the consideration of these general question Mach turns to his special problem, the psychology of sensation. The ideal of his effort he holds to be the determination of the 'connection of the psychologically observable data with the corresponding physical (physiological) processes' (p. 29). The guiding thread of such a research must be 'the principle of the complete parallelism of the psychical and physical' (p. 30).

It is but a step further to assume as many physico-chemical neural processes as there are distinguishable qualities of sensation (Pref. to Eng. ed.). Similar principles of research are largely admitted and follow naturally from the concepts of Bell and Müller. But the question remains open as to whether different qualities of sensation are to be related to numerically different structures, or whether likeness and difference of mental status are to be related to qualitative likeness and difference of physico-chemical processes taking place in nervous structures whose numerical distinctness, even if existent, is accidental. Mach declares himself for the latter hypothesis, and an illustration is furnished in his treatment of tone-sensations. If, in this field, we look, with Helmholtz, for a special end organ corresponding to each pitch, likeness and difference of tones mean the excitation of the same and of different end organs, a point of much consequence in the theory of harmony. If, on the other hand, we regard the quality of the process that takes place in an end organ as a factor in the result, we might assume with Mach that every end organ is the seat of two kinds of energies (say a 'Dull' and a 'Clear'), the various ratios in which the two are excited being the physiological determinant of the pitch (pp. 128, 143, etc.). Two notes may then be more or less alike, although dependent upon numerically distinct end organs, since each involves the same two specific 'energies,' only in different ratios. Mach is thus enabled to give a physiological basis to that theory of harmony which makes it depend upon the presence of common overtones. All tones are more or less alike; harmonious tones are more alike than others, because their common (physiological) overtones reinforce each other (p. 144, ff.).

The particular tone theory presented by Mach, although highly ingenious, and although it has won for itself some protagonists (*e. g.*, Wundt), becomes a little strained when we try to explain why two simple tones of different pitch are not identical with one tone of intermediate pitch (p. 129). Still the general principle of sense physiology, on which the theory rests, is of the greatest interest. Those who would object that progress in the physiology of the senses has been in the direction of differentiating numerically distinct structures corresponding to

qualitative differences of mental states, must square their antipathy to Mach's theory with the prevailing acquiescence in the view that regards intensity differences as adequately explained by relating them to differences in the energy of excitation of the same physiological structure. It is only a step further to explain differences of quality by relating them to differences in the *ratios* of the energies involved in the excitation, either of the same, or of similar structures. Either our psychology of intensity must be brought into line with the progress of qualitative differentiation or the field must be left open to such theories as that of Mach.

The reviewer agrees with the translator that the matter contained in Mach's little work is by no means so limited as the number of pages. He offers this as an excuse for having passed over many points in the discussion more lightly than their importance deserved.

EDGAR A. SINGER, JR.
UNIVERSITY OF PENNSYLVANIA,
August, 1897.

SOCIETIES AND ACADEMIES.

ENTOMOLOGICAL SOCIETY OF WASHINGTON.

OCTOBER 14, 1897.—Mr. Schwarz spoke of the remarkable collection of insects recently made by Mr. H. G. Hubbard in southern Arizona. This collection is the most extensive and valuable which has been made in that part of the country. In Coleoptera alone it contains between 300 and 500 species new to the fauna of the United States. He exhibited a specimen of the myrmecophilous Scarabæid *Lissomelas flohri* Bates, a genus new to the United States and allied to Cremastochilus. The specimens collected by Mr. Hubbard were not found in ants nests, nor could any traces be found of thoracic glands which are supposed to be attractive to ants. The insect fauna of Arizona and southern California was discussed at some length by Messrs. Schwarz, Gill and Fernow. Mr. N. Banks exhibited specimens of *Chrysopa ypsilon*, each of which carried one or more minute Cecidomyiid flies on its wings. The specimens were collected by Mrs. Slosson in the White Mountains, and Mr. Banks considers that the Cecidomyiids use the Chrysopas as a means of locomotion. Mr. Ashmead mentioned a parasitic wingless fly of the family Borboridæ collected by Mr. O. F. Cook in Liberia, which uses a common snail for transportation purposes. Mr. Ashmead described a new genus of Cynipidæ from Liberia which he will call *Curriea*, after the collector, Mr. R. P. Currie. It is the only genus of the Cynipidæ with toothed hind femora, and bears a superficial resemblance to certain Chalcididæ. Mr. Howard read a short paper entitled 'Notes on the House-fly,' which gave rise to a discussion on the carrying of contagion by house-flies, in the course of which Mr. D. G. Fairchild described at some length a serious eye disease prevalent in the Fiji Islands, which is carried by the house-fly. Mr. N. Banks read a paper entitled 'A New Species of the Genus *Halarachne*,' the typical specimens of which had been taken from the bronchial passages of a seal which had died in the National Zoological Park. Mr. Ashmead read a paper entitled 'On the Genera of the Xyelinæ.'

November 4, 1897.—Mr. Ashmead showed specimens of the male of *Pelecinus polyturator* from Indiana. The female of this species is very common, but the male is extremely rare. Mr. Ashmead thinks that this insect, the habits of which are not yet known, is probably parasitic upon some Coleopterous wood-borer, a conclusion which was discussed at some length by Messrs Schwarz and P. R. Uhler. Mr. O. F. Cook exhibited specimens of *Peripatus novazealandica* and of two small species of *Peripatus* from the Bismarck Archipelago. Mr. Schwarz exhibited specimens of *Cychrus mexicanus* Bates, a species new to the fauna of the United States, captured by Mr. H. G. Hubbard, at Cave Creek, Arizona. Mr. Howard exhibited specimens of *Trypeta acidusa* Walker, reared from ripe peaches by Mr. A. Koebele, at Orizaba, Mexico, and spoke of the Mexican distribution of *Trypeta ludens*. The subject of the possible establishment of these fruit pests in the United States was discussed by Messrs. Howard and W. G. Johnson. Mr. O. Heidemann read a paper on 'Hemiptera found on the Ox-eye Daisy,' listing twenty-nine species and giving notes on their habits. Mr. O. F. Cook read a paper on 'New Dicellura,' an order which he has erected to include the allies of Japyx. He exhibited plates of ten species and showed specimens of a new

African form which he thinks will form a new family in which the forceps are replaced by stylets. Dr. H. G. Dyar read a paper on 'Some Structural Points in Saw-fly Larvæ.' Mr. N. Banks presented a paper on an 'American Species of the Genus *Cæculus*,' a genus new to the United States and previously known only in Europe. Professor P. R. Uhler exhibited a series of American Notonectas and spoke of the distribution and structural peculiarities of the genus. As a result of the recent studies of Mr. G. W. Kirkaldy nine valid species are now known from the United States.

L. O. HOWARD,
Secretary.

BIOLOGICAL SOCIETY OF WASHINGTON—281ST MEETING, SATURDAY, NOVEMBER

PROFESSOR LESTER F. WARD exhibited specimens of *Prosopis juliflora* from Kansas, a species not previously found in the region of Gray's Manual; also of *Psoralea tenuiflora*, remarkable as a tumble-weed, and of *Lotus americanus*, a peculiar 'compass-plant.'

Mr. E. L. Morris showed some alcohol specimens of various vertebrates and invertebrates illustrating methods of sectioning to show the alimentary canal.

Mr. Charles L. Pollard presented 'A Publication Problem in Botany,' drawn from Rafinesque's Florula Ludoviciana. This book was practically compiled from the list of plants given by a Frenchman, Robin, who had traveled extensively in Louisiana, and had made numerous field observations and descriptions. Rafinesque based many of his new genera and species on these field notes, never having seen any type material, and Mr. Pollard asked for an expression of opinion on the tenability of these names, explaining that botanists of the present day are divided on the question. The consensus of opinion in the Society, elicited by discussion, favored the retention of the names in all cases where they were identifiable.

Dr. M. G. Motter presented a paper on 'Underground Zoology,' being the result of a careful examination of a large number of disinterred human bodies with a view to ascertain the species of animals and particularly of insects that might be present in order to test Mégnin's 'Application of Entomology to Legal Medicine.' Some 75 species belonging to 60 genera were noted and the conclusion drawn that so far as the evidence of his observations was concerned the medico-legal aspect of cadaverine entomology was enveloped in a haze of uncertainty, not to say doubt.

Mr. F. A. Lucas spoke of the 'Fossil Bison of North America,' saying that while remains were widely scattered over the United States the species were known mostly from horn cores, and owing to lack of correlation of these with other parts they could not be satisfactorily diagnosed. He recognized six species besides *Bison bison*, viz.: *Bison alleni*, *antiquus*, *crassicornis*, *ferox*, *latifrons* and *scaphoceras*. *B. crassicornis* of Richardson, which had been confounded with various species, was perfectly distinct, while *B. crampianus* was probably synonymous with *B. alleni*.

Dr. C. Hart Merriam described the 'Life-zones of the Olympic Mountains,' noting the flora and fauna of the region at some length. But two zones were distinguishable, a Hudsonian and a mixed Transition and Canadian.

F. A. LUCAS,
Secretary.

GEOLOGICAL SOCIETY OF WASHINGTON.

AT the 67th regular meeting of this Society, the first meeting of the course of 1897–98, held in Washington, D. C., on November 10, 1897, Mr. Lester F. Ward read a paper on the Cretaceous Formation in Southwestern Kansas. Mr. Ward had made a study of the Cheyenne formation, as well as of all the Cretaceous deposits in that region lying between the Red Beds and the Tertiary.

The principal section lay along the Medicine Lodge River, extending from a point near Sun City, in Barber county, to Fullington's ranch, near the extreme head of that stream, in Kiowa county. The center of operations was at Belvidere, and all of the most typical exposures of the Cheyenne occur within a radius of ten miles from that point. A reconnaissance was also made to the southwest as far as the Avilla Hill, five miles south of the town of Avilla, in Comanche county, and thence northwestward to Mt. Nebo, St. Jacob's Well, the Big Basin,

and the various draws and breaks on Little Sandy creek, Chatman creek, Bear creek, Bluff creek and Hackberry creek, where the Cretaceous formation, is extensively exposed. The following is a brief summary of the general results:

The Cheyenne formation rests everywhere unconformably upon the Red Beds, occasionally with a gravel bed at its base. It is a good geological unit, clearly marked off from the overlying Kiowa, the lowest member of which forms a thin ledge of marine shells, the Champion of Cragin. The lower part of the Cheyenne is almost always a massive sandstone, often cross-bedded, pure white, or more frequently stained yellowish. It contains no admixture of clay, but occasional thin clay shales, and very rarely more or less lignite. Near its base silicified wood occurs, at some points in considerable abundance. This bed, No. 1 of Hill, the 'Coral Sandstone' of Cragin, varies greatly in thickness, but where well preserved reaches 50 feet. In typical exposures this is overlain by some 15 feet of carbonaceous shales, consisting largely of dark, sandy, stratified clays, much lignite, and abundant vegetable remains, usually matted and confused so as to yield few determinable impressions. This is the No. 2 of Hill's section, the 'Lamphier Shales' of Cragin. Above this is the 'Stokes Sandstone' of Cragin, Hill's No. 3, having a thickness of some ten feet and consisting of stratified sandstone of a somewhat darkish or grayish color, considerably argillaceous and carbonaceous and often holding plant impressions. The character and relations of these upper beds, however, were found to vary so extensively that this subdivision has very little value. A large collection of fossil plants, amounting to 44 boxes, with an aggregate weight of about 3,000 pounds, was made in these upper beds and has been received at the U. S. Geological Survey.

The Cheyenne is confined exclusively to what may be called the Belvidere region, chiefly along Medicine Lodge river, as above noted, but passing southward along the head of Elk creek, across Mule creek and Indian creek, some six miles southeast of Nescatunga, forming a sort of crescent. It does not occur in the Avilla Hill nor anywhere in Clark county, so far as Mr. Ward was able to observe; the rocks of the former region, supposed by Prosser to represent the Cheyenne, being wholly different and belonging to the lower Kiowa beds, underlain by black papyraceous shales; and the Big Basin Sandstone, which Prosser also referred to the Cheyenne, being clearly, as Cragin states, nothing but the upper indurated portion of the Red Beds, the top of which is almost always whitened.

Perhaps the most important result of this expedition was the discovery of the true base of the Dakota group in a series of remarkable beds, nearly 200 feet in thickness and not hitherto described, forming an uninterrupted transition from the Kiowa Shales, holding Gryphæa and Exogyra, to the typical Dakota Sandstone, yielding characteristic dicotyledonous leaves, a small collection of which was made. Mr. C. N. Gould, who was a member of Mr. Ward's party, and who had previously seen most of these deposits, will soon publish a paper setting forth their relations in detail.

Under the title 'The Geological Sequence in Jamaica,' Mr. Robert T. Hill presented an account of the stratigraphic succession in Jamaica, describing the various rocks of igneous, sedimentary, oceanic and organic origin and their relations. Mr. Hill's paper was an extract from his report to Professor A. Agassiz, under whose auspices the studies were made. In discussing the elevated coral reefs he stated that there can be no possible doubt but that they were formed around emerging land, as held by Agassiz.

W. F. MORSELL.

U. S. GEOLOGICAL SURVEY.

NEW YORK ACADEMY OF SCIENCES—SECTION OF GEOLOGY—NOVEMBER 15, 1897.

THE first paper of the evening was by Dr. F. J. H. Merrill, of the State Museum at Albany, entitled 'Geology of the Vicinity of Greater New York.' Dr. Merrill considered the distribution, relations and structure of the Crystalline, Metamorphic and Intrusive rocks east of the Hudson. He noted particularly in the vicinity of New York City the Pre-Cambrian Fordham Gneiss, overlain at certain places, as

at Lowerre, Hastings, Sparta and Peekskill, by a very thin bed of Quartzite, probably representing the Georgian Quartzite of Dutchess county. Above this is a thick series of Crystalline Limestones, forming the river valleys of the Harlem, Bronx and other rivers, and underlying most of the navigable water ways in the vicinity of New York. The upper rocks are Mica-schists, which are probably of Hudson River age, and make most of the highlands of New York City and vicinity. These rocks are extensively folded in a general direction of N. 40° E., with occasional cross foldings, producing the cross valleys. The whole series is crossed by the Manhattanville Fault, running from Manhattanville, North River, southeastwards to the East River, between Ward's and Blackwell's Islands, into Astoria Bay. The fault, along which there has been a throw of a number of hundred feet, was long ago described by Professor Dana.

The second paper of the evening was by Captain J. J. Riley, entitled 'The Guano Deposits of the Islands of the Southern Pacific, and their Prehistoric Remains.' Capt. Riley considered in detail the depth, value and manner of working of the guano deposits in the Chincha Islands, off the southern coast of Peru, from which guano was first taken by Humboldt in 1804, and which have since been very famous for their guano deposits. Between 1850 and 1880 it is estimated that guano to the value of $550,000,000 in gold was taken from three islands alone. The islands lie in the rainless region, and the preservation of the guano is due to the absence of water. Once in about seven years there is a season of quite a little rainfall, which has undoubtedly a great effect upon the guano, and was considered by Captain Riley to be the cause of the blacker bands in the layered deposits. Two burial tombs containing bodies of great antiquity have been discovered in the guano. The bodies were evidently those of royal personages, and apparently, from the evidence of slabs containing certain symbols, related to the Incas. These tombs were found at a depth of 35 and 68 feet, but it is not possible to state whether they were buried in the guano or later covered by it. The islands, three in number, are granitic in character, and were covered by a varying thickness of guano, reaching in the more important island a depth of 203 feet in places. The exportation of guano has, however, ceased since 1880.

In the discussion Dr. Julien compared these islands with other guano-bearing islands of the West Indies, paying particular attention to the absence of any evidences of human remains showing life coincident with the formation of the guano.

The third paper, read by title, was by Mr. Stuart Weller, and entitled 'A New Crinoid from the Coal Measures of Kansas.'

RICHARD E. DODGE.
Secretary.

BOSTON SOCIETY OF NATURAL HISTORY.

THE first general meeting of the season was held November 3d, seventy-five persons present.

Mr. J. B. Woodworth spoke of Mr. Saville-Kent's work concerning the Great Barrier Coral Reef of Australia. He sketched briefly the chief results of the studies of Darwin and others upon the theory of coral reefs and showed a series of lantern slides giving a general view of the life upon the Great Barrier Reef. This reef stretches along the coast for a distance of more that 1,200 miles; the distance from the outer edge of the reef to the mainland varies from 10 to over 100 miles. The reef and adjacent waters abound in Nullipores, Madrepores, Alcyonarians, Holothurians, etc. The pearl and pearl-shell, Trepang and oyster fisheries are of very great importance.

THE UNITED STATES FISH COMMISSION.

ACCORDING to law the United States Fish Commissioner must be a man of 'proved scientific and practical knowledge of the fishes of the coast.' If President McKinley judges that Mr. Cleveland violated the law in appointing to the position the cousin of a prominent Democratic politician, having no previous scientific knowledge or practical experience in the work, retired from the navy owing, it is said, to rheumatism, aggravated by sea air, and if further the incumbent has not during the past two and a-half years acquired 'scientific and practical knowledge of the fishes of the coast,' then it is the President's duty to remove the present Commissioner and make a new appointment according to the requirements of the law.

We think that the President could best secure information on the subject by appointing a committee of men of science to make a report on the conduct of the Fish Commission during the past two and a-half years. The National Academy of Sciences is the legal adviser of the government on scientific questions, and a commission consisting of President Gibbs, Mr. Agassiz and President Jordan could make a report, the

conclusions of which would be final. It is our belief that freedom of thought and action and permanent tenure of office are so important for the advancement of science that no scientific officer, whether of a university or under the government, should be removed except on the ground of incompetence publicly proved.

President McKinley may, indeed, judge that incompetence in the present Commissioner has been publicly proved by his record prior to his appointment and by his conduct of the Commission, and if he has reached this decision it would be hard to question its justness. The appointment was unfortunate, as is admitted by every one; and while the Commissioner has since learned somewhat of the practical work of hatcheries, it does not appear that he is willing to take scientific advice in regard to the conduct of the Commission. It must also be remembered that the education of the Commissioner, as far as it has progressed, has been very expensive, costing the government perhaps as much as to train a hundred young men until they were competent to fill the position.

Apparently the efforts of the Commissioner have hitherto been directed to collecting the largest possible quantity of eggs in order that he may announce the numbers in his annual reports. Thus the last annual report states that 128,000,000 lobster eggs have been collected during the year, being an increase of 46,000,000 over the numbers for 1895. We are not, however, told how many of these eggs were killed at the hatcheries, and the Commissioner is probably not aware that in taking the eggs from the hen lobster he materially interfered with their chances of survival. Scientific research has demonstrated that the lobster in berry, whose capture is prohibited by law, can care for the eggs far better than would be possible in any hatchery. To collect them as is done is analogous to taking all the babies born in New York City and depositing them in a baby farm. It is true that much might be accomplished by collecting the eggs in regions where they are abundant and depositing the young where the lobster has been nearly exterminated; but the Commissioner states explicitely 'that he believes in following nature as closely as possible, by depositing the young on the ground from whence the eggs are taken.'

Even at present the Fish Commission is performing a useful work in some directions, such as the distribution of shad fry, with results that more than repay the entire expense to the government of the Commission. But it is now living, not on income, but on capital. The scientific knowledge of the development, life histories and habits of fishes acquired when the Commission was directed by Baird, by Goode and by MacDonald is being used, but not increased. The efficiency of the hatcheries and of methods of distribution cannot be advanced or even maintained, and it is impossible to extend the work in needed directions, as to the oyster. It would be ignoble to depend on the work of foreign nations and investigators, even were it directly applicable to the conditions of our coast. But, indeed, the present Commissioner has not the knowledge to 'convey' what he cannot

earn. It is reported that recently, when he claimed that the station at Woods Holl was the greatest biological station in the world because it hatched the largest number of fry, he was reminded of the Naples station, but replied that he had not heard of it.

The station at Woods Holl, made by Baird, Goode and MacDonald a center of research, fruitful in practical applications, regarded as a model by other nations, has now fallen into disrepute. The institution has been practically closed to investigators. The present Commissioner is apparently unable to appreciate what such a station means and what great practical benefit might proceed from it. Scientific research and the applications of science are but the obverse and reverse of the same coin, and he who expects to do without one side of the coin will find that he has none left in his pocket.

Now since the Coast and Geodetic Survey has been reformed by the present administration, only the Fish Commission needs its attention. When Mr. Cleveland was Governor of New York he vetoed the bill for the continuation of the Geological Survey of the State, and when President he occasionally showed that he had too long postponed his university training. The present administration is, however, in full sympathy with the scientific departments of the government, and is competent to decide whether the present Commissioner meets the requirements of the law, and, if not, to appoint a Commissioner of 'proved scientific and practical knowledge of the fishes of the coast.'

THE NATIONAL ACADEMY OF SCIENCES.

THE autumn meeting of the National Academy was held this year in Boston, beginning at 11 a. m. on Tuesday, November 16th, and continuing until Thursday afternoon. The attendance of members was unusually large for an autumn meeting, about thirty being present at one time or another during the three-day session. The absence of some members residing almost within sight of the place of meeting was a noteworthy indication of a lack of great interest in the leading scientific organization of the country. The program of papers offered was also unusually long and varied, nearly every department of science being represented. While all of these contributions were valuable and taken together represented a large amount of original investigation, none could be considered as unusually or unexpectedly important or strikingly novel in character or results.

The session opened with Professor Woodward's paper on 'The Mass of the Earth's Atmosphere.' The general conclusions of interest were that the radius of the atmosphere was probably five or six times that of the earth, and that while its mass could not exceed five per cent. of that of the earth it was probably not more than one millioneth as much. Professor Carl Barus presented the result of further studies of the effect of time on the temper of steel, the beginnings of which he had published some years ago. The lapse of years has served to bring out more clearly the interesting and important secular changes, the recent measurements having been made on the same specimens used in the earlier stages of the investigation.

This paper was followed by that of Dr. Mendenhall on 'Steel Knife Edges,' which was also a continuation of researches communicated to the Academy at previous meetings. The present investigation

consisted in the main of an examination of the behavior of steel knife edges under pressure and with varying angles. By observing the electrical resistance of the surface of contact of the pressure plate and the knife edge, the effect of pressures varying from zero to twenty thousand pounds was determined, the length of edge being about two inches. The superiority of the wide angle edges was clearly shown, confirming the conclusion reached in previous investigations. Professor O. C. Marsh next gave an interesting account of recent visits to the Russian museums, in which, greatly to his surprise, he found no examples of dinosaurs. He held, however, that they would yet be found in the district represented by these museums.

Professor Chittenden presented the results of an elaborate investigation of the effects of borac and boric acid on nutrition, and Dr. Minot, who was formally introduced as a new member by the President of the Academy, having been elected to membership at the April meeting in Washington, read an interesting account of embryological investigations in which he has been engaged. Professor W. A. Rogers gave the results of his last determination of the relation of the yard and meter, depending upon a recent comparison of his own standard with one of the new prototypes in the Office of Weights and Measures at Washington. Professor Morse presented important results of the study of the ancient molluscan fauna of New England and Professor Verrill discussed cannibalistic selection as a factor in evolution.

The session on Wednesday morning was devoted to the transaction of business, members only being admitted. The important event of the session was the formal acceptance, by the Academy, of the gift of $20,000 from Miss Alice L. Gould, daughter of the late Dr. B. A. Gould, one of the charter members of the Academy. Miss Gould had communicated her intention of making this gift in honor of the memory of her father and of his long connection with and interest in the National Academy, at the April meeting in Washington, but on Wednesday the deed of gift was formally presented, together with the conditions on which it was made and the names of the first trustees. Its acceptance was authorized by the Academy and the trust assumed. The income of the fund is to be devoted to the encouragement of astronomical research and its management is to be essentially like that of the Bache fund. The trustees selected by Miss Gould were Professor Boss, Dr. S. C. Chandler and Professor Asaph Hall.

In the scientific session that followed, Professor Hyatt reported progress in an interesting study in which he is engaged, upon the migration of land shells on the Hawaiian Islands. The material for this study had been obtained from an extensive collection of shells made by Rev. J. T. Gurlick while a missionary in the islands thirty or forty years ago. This collection had been so systematically made and the locations so carefully noted that Professor Hyatt was enabled to lay out on a relief model the various localities occupied by different species, and to indicate the paths along which their migrations must almost certainly have been directed.

This paper was followed by an exhibtion by Professor Michelson of his new harmonic analyzer, which he had brought from Chicago to show to the Academy. In the latest form of the machine eighty elements were included, and it appeared to be capable of producing results correct to within about one per cent. The machine was put in operation, and its work, both in analysis and synthesis, was greatly admired. Mr. C. L. Norton presented by invitation a description of new apparatus, one for thermometer comparisons and the other for determining the heat of combustion.

A paper by Dr. Weir Mitchell and Alonzo H. Stewart, on the 'Action of Venom of Crotalus Adamanteus Upon the Blood,' was read by Dr. Bowditch.

On Thursday there were further contributions by Professors Verrill and Marsh. Professor Cross, on invitation of the Council, presented a paper on the 'Wave Siren,' and S. C. Chandler discussed the agreement of 'The Theory of the Motion of the Pole with Recent Observations.' There was also a paper by Major Powell, 'An Hypothesis to Account for Movements in the Crust of the Earth,' and Professor Emmons gave an account of the International Congress of Geologists at St. Petersburg.

As might well be expected, the social features of a meeting of the Academy were not lacking. A number of academicians availed themselves of the opportunity to hear the last of the course of lectures on 'Tides' by Professor George Darwin, at the Lowell Institute, the final lecture of the course being on Tuesday evening. There was unusual interest in the reception on that evening, at the home of Mrs. Professor W. B. Rogers, whose husband was for several years and at the time of his death the President of the Academy. Similar courtesies were extended to members on Wednesday and Thursday afternoons, and on Wednesday evening Professor Trowbridge described and exhibited his new 10,000-cell storage battery and high-voltage apparatus.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

THE 18th annual and 36th regular meeting of the American Society of Mechanical Engineers was held in New York, beginning on November 30th. This Society, now seventeen years old, numbers nearly two thousand members, including substantially all mechanical engineers of the United States. Its transactions are always rich in valuable technical facts and data and are usually so extensive as to fill a large annual volume.

The principal papers of the present session were the following:

Mr. F. W. Dean summarizes the progress of improvement in reducing the 'Cost of Steam Power' from 1870 to 1897; showing that the gain has been between thirty and forty per cent. He attributes this saving to the following: 37% to higher steam-pressure and ratios of expansion, multiple-cylinder engines, steam jacketing and drying or superheating the steam; 5% to the use of vertical engines; 7% to improved boilers; 7% to economizers heating the feed water; 2% to improved grates. The weight of steam used per horse-power per hour has fallen from 20 to 12.5 pounds, as minima for the dates given. He finds the compound engine the usual and on the whole most successful form of engine and gives valuable data relating to its efficiency and the costs of power where it is employed.

Professor Carpenter presents the results of 'Tests of Centrifugal Pumps' and 'Calibration of a Weir' at Chicago, where the unique opportunity was presented of making such determinations on an exceptionally large scale, and of checking the standard formulas for discharge perhaps more accurately than ever before on anything approaching so large a scale. The conclusion is reached that the Weisbach formula is more exact than the Francis, under such circumstances, and that it is best employed without allowing for 'end-contraction.' The great centrifugal pumps, of usual form, gave efficiencies rising to above 60 per cent.

Dr. Thurston, in conjunction with Mr. Brinsmade, read a paper on 'Multiple Cylinder Engines and Effects of Variation of Loads,' in which the experimental investigation of the relative efficiencies at various loads was determined for the standard 'compound' and 'triple expan-

sion' engines and for the peculiar form of engine produced by omitting the intermediate cylinder from the latter, thus producing a machine with abnormally high ratio of cylinder-volumes, as successfully employed by Rockwood. A wide range of load was adopted and the result is found to be an efficiency, in the case of the novel form of engine, intermediate between that of the triple-expansion and that of the standard compound, approaching the efficiency of the latter as maximum expansions and minimum loads are approximated. We may be able to give later a fuller abstract of this paper.

Mr. W. S. Keep details a series of experiments upon 'Cast Iron under Impact,' in which he shows some very singular and puzzling phenomena, such as the increase of the strength of the metal by simply smoothing its surface, variation of the resistance and of the elastic limit by such alterations of its superfices, and similar hitherto unsuspected modifications of its molecular characteristics by this method of strain.

Mr. George Richmond offers a study of 'Thermodynamics without the Calculus,' in which he develops in an interesting and peculiarly helpful manner the method of Professor Gibbs in the application of the temperature-entropy system of coordinate, thermodynamic geometry. The paper is presented in compliance with the request of members of the Society in the course of a discussion during the preceding meeting.

Mr. Charles T. Main gives a very unique paper, on the 'Valuation of Textile Manufacturing Property;' which important but greatly neglected department of technical literature has peculiar interest to the capitalist and the economist as well as to the engineer. This study is in great detail, and its writer is an acknowledged expert.

Mr. Fletcher submits an account, given by the inventor, who is still living at a ripe old age, of the invention and introduction of the Stevens Valve-Gear for steam engines, universally employed for many years past on the 'American river-boat engine.' It is an interesting and valuable contribution to technical history.

Other papers, numbering in all over twenty, are contributed by as many members, each expert in his own department, and affording material for another valuable volume of transactions.

The next meeting will probably be at Niagara Falls.

PRESIDENT GILMAN ON THE RELATIONS OF SCIENCE AND COMMERCE.

At the annual banquet of the Chamber of Commerce in New York, November 23d, the chairman, Mr. Alexander E. Orr, called upon President Gilman, of Johns Hopkins University, to respond to this sentiment, *Commerce the Child of Science and its filial Supporter*. The substance of Mr. Gilman's remarks is indicated in the following report:

Let me give some striking illustrations of the impulse that Commerce has received from Science; but let them all be drawn from present times, at least from days with which many men in this assembly are personally familiar.

Without astronomy there could be no sure navigation of the open sea. The great observatories, with their able masters and their powerful lenses, are revealing to human intelligence the celestial mechanism, and are making every year more accurate the nautical almanacs—those guides to the heavens, so sure and so important that we may almost call them 'The Pilots' Bible.' It is to the science of naval architecture that commerce owes the marvelous improvements which have transformed the packets of the 'Black-ball' line and the Baltimore clippers into the iron steamers of to-day. The size, materials, forms, structure, of sea-going ships, both men-of-war, protectors of

commerce and the great liners of the ocean, are the results of careful study, by able men in quiet hours, devoted to the ascertainment of accurate knowledge.

It is the science of mechanics which has developed the steam engine for the feeble motor, plied by Fulton on the Hudson, into the triple and quadruple expansion engines which now propel these enormous steamers, to and fro, across the ocean, with a regularity almost as sure as the swinging of a pendulum.

Geographical science has studied every portion of the globe and opened to commerce the continents of Africa and Australia, and the islands of Japan and Oceanica, closed to Europeans before the days of Wilkes, Perry, Stanley and other explorers.

It is to hydrography that commerce owes the accurate surveys of coasts, channels and harbors, initiated in this country by the Blunts, those once famous New Yorkers, and those surveys of the ocean depths which made possible the laying of the Atlantic Cable.

Physics has well fulfilled its part by the improvements introduced into the construction of the mariners compass, the propelling screw, the perfection of light houses, the introduction of fog signals, and the ever advancing development of electro-magnetism, most significant, far reaching, revolutionary and serviceable of all modern discoveries.

Meteorology, a branch of physics, grows more accurate every year and is interpreting and foretelling the course of winds and cyclones.

Almost all these advances lie in the field of mathematics.

Cancel these gifts of science. Restore electricity to the excitement of a bit of amber, bring back the quadruple expansion engine to the tea-kettle from which it has been evolved, reduce the nautical almanac to a deliniation of 'the Dipper,' and destroy the charts on which reefs and shoals are carefully indicated to the rude outlines of even fifty years ago—and where would commerce be?

Now let us change our point of view and see how these obligations have been met. With open-handed munificence, with horns of plenty filled with the products of every clime, Commerce, the child of Science, has been her generous supporter. Rapidly glance at the record.

It was an East Indian merchant

> Born in America, in Europe bred,
> In Africa travelled and in Asia wed

made those gifts to the collegiate school in New Haven, which have given renown for almost 200 years to the name of Elihu Yale. The last half century has been prolific in kindred gifts. It was a merchant of Mobile who founded the Sheffield Scientific School in New Haven; a merchant of Boston who gave his name to the Lawrence Scientific School in Cambridge; a merchant of New York who established the John C. Green School of Science in Princeton; a merchant of Brooklyn whose gifts to Cornell University surpassed the founder's; a business man of Philadelphia who founded the Towne School of Science; a merchant of New Orleans whose name is recalled by Tulane University; and a merchant of Baltimore, Johns Hopkins, who divided his fortune between a university and a hospital.

Just so with modern libraries in this country. John Jacob Astor, a merchant of New York, set the example, soon to be followed by Lenox and Tilden. Joshua Bates, a partner of the Barings, rendered a like service to Boston, and William Brown, one of the Brown Brothers, to Liverpool. The museums at Cambridge and New Haven attest the scientific interest of George Peabody, who founded a library in Baltimore. Chittenden, of New York; Pratt, of Baltimore; Newberry, of Chicago, each one a mer-

chant, and a great many more, are the builders of libraries, which Carlyle once called 'the true universities.' When Western learning is needed in Turkey and the Levant, it is a merchant of New York who founded Robert College, near Constantinople, and another merchant, William E. Dodge, and his associates, who established the Syria College of Beirut. When it was a question of Arctic research Henry Grinnell and George Peabody equipped the expedition of Kane and his successors, and when a museum of natural history was required, or a gallery of fine arts, it was from the members of this chamber that support was secured. Thus commerce generously has contributed to the maintenance of learning. Is it not that the pursuit of commerce broadens the mind? To promote among the nations of the earth those exchanges which benefit alike the buyer and the seller enlarges human sympathy. The study of the world's resources, requirements and conditions of prosperity produces wisdom, courage, forethought and generosity.

PRIMITIVE MAN IN THE DELAWARE VALLEY.*

INTRODUCTORY.

A FEW years ago, as a result of extended explorations, conducted by the Bureau of American Ethnology, questions were raised with reference to the soundness of the then existing evidence relating to glacial man in the Eastern States, and the correctness of the conclusions drawn from it. Since that time, until quite recently, investigation has progressed slowly and but little has been brought forward likely to change the status of the case. Now, however, strong claims are being made of the discovery of new and confirmatory evidence of antiquity, and discussion is invited with a view of determining its merits; but before taking up this phase of the subject it is desirable that the earlier phases of the investigations be passed briefly in review.

*Read at the Detroit meeting of the American Association for the Advancement of Science.

The questions raised by me were not those of the age of man in America. I have always taken the view that the race must have occupied this continent for a very long period. Great antiquity is clearly proved by facts derived from other than archæologic or geologic sources. It does not require argument to show that the development of many well differentiated nations and tongues means a prolonged occupation. It does not take argument to demonstrate the proposition that, notwithstanding the potent influence of local environment upon human art and effort, a thousand distinct cultures could not spring up in a day.

The only questions I have ventured to discuss and the only ones that now claim my attention are as to whether the evidence already brought forward to demonstrate the antiquity of man on the Atlantic slope will stand the test of scientific scrutiny. There is a record of man in the valleys and among the hills throughout the entire country. There is an important record in the geological formations of the Delaware valley. Has the key to this record been discovered? Has the true combination been worked out, or are our pioneer investigators struggling through a phase of this particular research corresponding to that encountered by the predecessors of Champollion in the reading of the Egyptian hieroglyphs? The earlier readings at Trenton seem to indicate possibly three distinct peoples and periods of occupation, referred to by some as paleolithic, Eskimo and Indian; but are we sure of more than one and are the others mere figments of the imagination? Time will tell, but this year or the next may not finally decide it.

THE ALGONQUIAN OCCUPATION.

The first step in acquiring a knowledge of the past is to seek to understand the present. An acquaintance with the historic peoples of a region is the best key to the prehistoric peoples. In the study of the question at issue in the Delaware valley correct method demands that we look first to known conditions for explanations of all doubtful phenomena. The only occupants of this region known to us were a group of Indian tribes of what has come to be known as the Algonquian stock. The history of these tribes, as dimly shadowed forth by tradition and archæology, extends back indefinitely into the past. They were found by the whites living in villages, cultivating corn, navigating the waters, hunting, fishing and warring; weaving simple fabrics, practicing the potter's art in its most primitive form, and employing stone as the chief material for implements and weapons. They used metal to a very limited extent and employed shell, bone and wood in various arts. Their culture status is made clear by actual observation of the peoples themselves, as well as by a study of the relics of many village sites known to have been occupied by them. The local tribes, the Leni Lenape, had relatives of like culture extending along the coast from Carolina to Maine and from the mouth of the St. Lawrence to the head of the Great Lakes. They had neighbors of other stocks, all occupying about the same simple level of neolithic culture. Researches long continued in the whole vast territory occupied have developed no definite trace of other people or other conditions of culture. No one can say how long they had been here or whence they came, but their coming was doubtless long ago. Wandering bands pushed their way over the hills or along the shores and gradually took possession of this beautiful region. One group, known to us as the Delawares, occupied the Delaware valley, adopting it as a permanent home. Their dwellings were established along the banks of the rivers and creeks; they multiplied and spread, and, being an active and enterprising race, gradually acquired a knowledge of the resources of the country, and especially of the varied mineral products, which were of the utmost importance to their welfare. On local sites they worked the varieties of stone available for implements. They dug them out of the loose deposits of the stream beds and bluffs. They advanced into the hills and mountains, and little by little discovered the deposits of desirable rock in place, and quarried deeply into the bowels of the earth. The work of search and exploration was so thorough that nothing escaped them, and the archæologist looks with amazement on the still existing evidences of their energy in quarrying argillite, jasper and soapstone.

The stones available to such a people in the earlier periods of their occupation would be the loose cobbles and masses of the rivers and bluffs. In the Trenton region the only material well fitted for flaking—the chief shaping process of the early days—was argillite, a compact slaty-looking rock especially plentiful in some parts of the glacial gravels. It follows that on and about the margins of the glacial terraces flaking at first dealt chiefly with this material. The beds of argillite found in place farther up the valley would next be utilized and later the flints and jaspers of the distant uplands would be discovered and used. How long it was from the time of the first occupation to the period of complete exploration and utilization of resources thus outlined no one can guess. It may have been 500 or it may have been 5,000 years. During this prolonged period the work of shaping stone implements went on. The raw material was sought and worked up with a persistence and energy that might

almost be regarded as a foreshadowing of the vast mining and manufacturing industries of to-day. The knives, scrapers, drills, projectile points, etc., the implements upon which everything in the savage economy depend, were roughed out, specialized and carried away, and the refuse in vast quantities, consisting of flakes, fragments and failures representing all stages of development, was left upon the ground. The rejectage must have been especially plentiful along the bluffs at Trenton, where the argillite was found in the shape of bowlders and partially worn masses, and in the valleys and hills above, where it occurs in place. The rude rejected forms left upon these sites were large or small, long or short, according to the shape of the implement made and the nature of the material used. They were rough or well developed according to the stage of the shaping process at which they were cast aside. No type of flaked stone has been found in the whole region that was not necessarily produced again and again and for centuries along the banks and bluffs of the Delaware by these historic peoples, and in the course of years and geologic mutation it is readily seen that this rejectage of implement-making would become intermingled in various ways with the superficial deposits of the sites of manufacture. Every bank that crumbled, every grave dug, every palisade planted, every burrow made, every root that penetrated and every storm that raged took part in the work of intermingling and burial; and following in turn came the resettling, the leeching-out and the recementing of these deposits, making it difficult to distinguish the old from the new. It follows, therefore, that the student of the history of this valley, and especially of that part of it recorded in the soil and superficial deposits, should not for a moment lose sight of these conditions and events of recent and comparatively recent history, and should seek first to explain all phenomena from the point of view thus afforded before conjuring up shadowy images of other races.

INVESTIGATION IN THE GLACIAL GRAVELS PROPER.

It happened, however, that before the investigation of the phenomena referred to above and now so definitely assigned to the Algonquian peoples had begun to attract the attention of archæologists the presence of other people had already been assumed. Evidences of very primitive paleolithic races had been associated with glacial formations abroad, and the glacial deposits of the Delaware region were accordingly searched with the hope of finding similar traces. Relics of art were soon secured, and as they were rude and exclusively of flaked stone they were regarded as supporting the theory of a glacial paleolithic man. A large body of evidence was soon accumulated and passed into literature without particular scrutiny.

When, finally this subject came into prominence and questions began to arise as to the determinations made, it was found that the flaked stones which formed the exclusive evidence furnished, though rude as reported, were not of special or peculiar types, such as seem to characterize paleolithic times abroad, but that they corresponded in every particular with the ordinary rude work, and especially with the rejectage of manufacture, of the Algonquian and other American tribes; and it happened further that they were found along the very bluff faces where argillite bowlders outcropped and where the Indian tribes had naturally resorted to secure the raw material and block out their implements; then it came to be asked whether the finds had really been made in the true gravels, whether they were not obtained from deposits associated with the gravels but not belonging, in their present deposition, to

the glacial age; such deposits as accumulate in depressions, or along the faces of bluffs and banks subject to crumbling and sliding. When later it was realized that the questions involved, the nice discriminations to be made in collecting this evidence, were really geologic rather than archæologic a new phase of the investigation was initiated and geologists were asked to participate in the examinations. It was imperatively demanded that the gravel should be reexamined and the evidence sifted and placed on a safe footing. In meeting this demand for re-examination of their evidence the advocates of an American paleolithic man have claimed that the criticisms made were to be classed with those encountered by Boucher de Perthes when he began to present his evidence regarding early man in Europe; that such criticisms meet every advance of thought. But the cases are by no means parallel. The discoveries of Boucher were not acceptable because of their revolutionary character with respect to accepted beliefs. On the other hand, the Trenton determinations were popular and almost universally accepted as final until attention was called to the true nature of the objects found, and especially to the unsatisfactory methods pursued in collecting evidence. The climax came when it was understood that the advocates of a glacial paleolithic man were gathering all classes of rudely flaked stones from the surface of the country generally (entirely disregarding an Indian occupation) and employing them to establish a peculiar theoretic culture for America.

It was not conservatism, and especially it was not conservatism in religious thought, that led such men as Powell, Brinton, McGee, Chamberlin, Salisbury, Mercer, Mason and others intimately acquainted with the field of investigation to seriously question the methods and the evidence. The charge of conservatism must rather be urged against

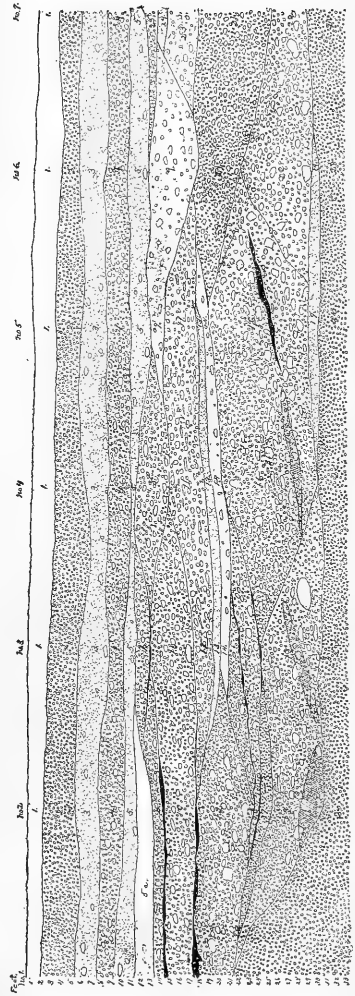

FIG. 1. Section of the Trenton gravels showing relation of productive to non-productive profiles.

those students who have held to their original views and especially against such scholars as Topinard, Boulé and Keane, who accept without serious scrutiny any evidence that tends to confirm accepted theories with respect to a uniform history of the race on both sides of the Atlantic.

Fortunately opportunities for a re-examination of the evidence have arisen in several cases. The principal discoveries of shaped stones attributed to the gravels were made in the slope of the bluff facing the river at Trenton (*A* in the section, Fig. 1) and in the banks of Assanpink Creek at the point where the Pennsylvania railway makes its way from the station near the creek level to the terrace above (*B* in the section). Finds continued to be made in the crumbling river bank at *A* until accumulating city refuse covered up the deposits.

They ceased to be made in the creek banks at *B* as soon as the cutting extended fairly into the gravels in place; and when, in 1889, I asked the principal explorer of this locality why the finds had ceased, he replied that when the railway cutting was made the excavations were carried up through a depression that must have been an old stream bed, and that the finds were in the filling of this channel. I do not think he understood the significance of the admission, but the statement must have been true, as nothing whatever is to be found in the present excellent exposures of the true gravels. The position of his finds are indicated at *d* on the dotted original profile in the section, and the present utterly barren exposures, half a mile or more in length, are indicated at *e*.

Identical results have been reached on the river front *A*. In 1892 a great sewer trench, *C*, 33 feet deep, was cut, parallel with the river bank, at the very point where so many shaped stones had formerly been found. Though we kept up the search in this trench for five weeks as the work of excavation went on—the whole body of gravel being subjected to rigid examination—not a chip was found, not a trace of man. No other examination has been made that compares with this for thoroughness and length of time involved. The evidence thus furnished has been spoken of as negative and hence as unsatisfactory, but, in the continued absence of finds of implements at this and other points, it seems positive and convincing. The conclusion reached is that there must have been an error in the observations that could produce hundreds of flaked stones from obscure or partial outcrops at a given spot in a crumbling bank when not a trace can be found at the same point when the beds are fully exposed.

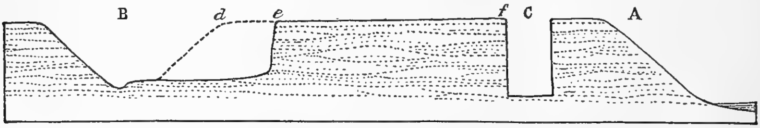

FIG. 2. Portion of section of gravels exposed in sewer trench, fac-simile of the original notes by Mr. Wm. Dinwiddie.

Geologists will be interested in seeing the detailed section made by my assistant in the trench. It tells the story of the deposits better than any other section that has been or probably ever will be made.

Considering the foregoing facts, it may be regarded as substantially proved that the glacial gravels proper contain no relics of art, and it would appear that now very few persons, indeed, expect them to yield any evidence whatever on the subject of human occupation. Five years have passed since the earlier observations and finds.

were challenged, and in that time, so far as I have learned, no single implement has been reported from the gravels, although the exposures are as extensive as they ever were. The first chapter in the prolonged search for glacial man at Trenton may, therefore, be regarded as practically closed; but some new evidence furnished by examination of certain superficial deposits of sand come up for consideration. My remarks upon this subject will appear in a subsequent number of SCIENCE.

W. H. HOLMES.

U. S. NATIONAL MUSEUM.

ON SOME IMPORTANT SOURCES OF ERROR IN THE PLANKTON METHOD.

THE Hensen method of plankton collection consists essentially in drawing a silk net vertically through the water. A part of the column of water traversed by the net is pushed aside, hence the actual catch must be multiplied by some factor to obtain the amount of plankton present in the given column of water. This factor, 'the coefficient of the net,' has been calculated by Hensen, for a series of velocities, from empirical data, and is applied uniformly to all catches without regard to the character of the plankton. The coefficient of the net used at the Illinois Biological Station, according to Hensen's formula, is 1.32 (velocity 0.5 meter per second). A series of field tests in which a column of water, similar to that traversed by the net was pumped and strained, indicates that the coefficient of the net varies with the amount and constituency of the plankton, ranging in the case of our net from 1.5 to 5.7. This variation is, in part at least, due to the increased clogging in the case of heavy planktons. The effect of the progressive clogging upon the coefficient is shown in a series of horizontal hauls of 5, 10, 15, 20 and 25 meters, which were made successively in similar water. The coefficient rose from 1.5 in the 5-meter haul to 4.83 in the 25-meter haul. A comparison of 15-meter hauls with those of 30 meters indicates that from 84% to 96% of the 30-meter catch is taken in the first 15 meters of the haul. Four places of decimals in a computed coefficient can hardly offer compensation for an error so fundemental as the variation in the straining capacity of the net. This error can be avoided by adoption of the pumping method and straining of a known quantity of water.

The plankton method as elaborated by Hensen and others depends upon the efficiency of the finest silk bolting cloth in removing the contained organisms from the water which it filters. It has been accepted by planktologists that the use of this cloth furnishes a satisfactory basis for the volumetric determination of the plankton and the enumeration of its constituent organisms. Hensen* (p. 75) states that the openings in the silk are so small that not many organisms can pass through them. Apstein† (p. 235) says: "With nets of this cloth almost all organisms are caught, only a few diatoms, which happen to meet an opening with their long axis, escape." Again‡ (p. 35) he maintains that almost all organisms are removed from the water by the use of No. 20 bolting cloth. No protest has been raised by our American workers§ || to these claims of the founders of the plankton method. The leakage of the plankton through the silk has thus been minimized or ignored, and without tests of the extent to which it occurs.

|| H. B. Ward. A Biological Examination of Lake Michigan. Lansing. 1896.

The bolting cloth (No. 20), when new, contains from 5,100 to 5,600 meshes per square centimeter, varying with the maker and the sample; when thoroughly shrunken the number of meshes increases as much as 30%. The total area of the openings in a square centimeter, on the other hand, decreases over 50%, falling from .133 to .066 sq. cm., and the average area of a single opening is reduced from .000024 to .00001. sq. cm. This latter figure represents an area of $32 \times 32 \mu$, the average area of the openings at the maximum efficiency of the silk. These dimensions do not, however, constitute a precise limit to the size of objects which can escape through the openings, for many meshes exceed this area, and some even double it. The struggles of the imprisoned organisms and the pressure of the filtering water also materially assist the escape of the planktonts through the yielding meshes of the silk.

For the past year and a-half the leakage of the plankton through the silk has been a subject of experiment at the Illinois Biological Station. The results were at first so surprising as to require the most careful corroboration, and they have been witheld from publication in the hope that an adequate remedy might be offered therewith. Water from a number of sources, collected at different seasons of the year, and containing plankton varying in amount and constituency, has been subject to examination in several ways, and their relative efficiency determined by the Sedgwick-Rafter counting method. In order to reduce the error incident to this process, the enumeration of the planktonts was extended over from five to ten times the customary fraction of the catch. The leakage has been tested as follows: by the Sedgwick-Rafter sand filter; by hard-pressed filter paper; by the centrifuge, and by the Berkefeld filter. The silk catches were made from measured quantities of water, thus eliminating the uncertainty as to the amount of water which the drawn net filters. Tests were made of the filtrate from the silk, and also of the unfiltered water. Owing to diversity in the constituency of the plankton, the ratio of efficiency of these various methods cannot be precisely stated. In a general way the order above given is that of increasing efficiency. The silk, *in the pumping method of collection*, retains from 5% to less than 0.1% of the total *number* of organisms present (excluding bacteria), as contrasted with the catch of the Berkefeld filter.

The Sedgwick-Rafter sand filter was used according to the published directions of Calkins,* and later of Jackson† and Whipple‡. This method is far more efficient than the silk, but proved to be subject to considerable loss, especially in the case of water richly charged with plankton. Not only do the minute forms, as *Raphidium* and the smaller diatoms, readily slip through the sand, but also the more active species, as *Euglena* and *Trachelomonas*, escape in considerable numbers. Examinations of the filtrate from the sand revealed the fact that this method captures from 40% to 65% of the number of organisms present, the greater losses occurring with abundant planktonts.

The filter paper employed was No. 575 Schleicher & Schüll. It is very free from lint and does not easily tear when wet. As the filtering proceeds the plankton is condensed in the bottom of the funnel by means of a fine spray from a hand bulb. When the required condensation is reached the plankton can be washed from the paper by the

*G. N. Calkins. The Microscopical Examination of Drinking Waters. 23d Ann. Rep. Mass. Board of Health, for 1891.

†D. D. Jackson. On an Improvement in the Sedgwick-Rafter Method. Technology Quarterly, Vol. IX. 1896.

‡G. C. Whipple. Experience with the Sedgwick-Rafter Method. Ibid.

same means, care being exercised in removing the plankton quickly and thoroughly to reduce the loss occasioned by its adherence to the paper. This method is very simple, rapid, and, in my experience, more efficient than the sand filter, yielding from 75% to 85% of the planktonts.

The centrifuge at first employed was a small one having a capacity of 60 c. cm. Later, we had constructed for this work a large machine geared to give 3,000 to 4,000 revolutions per minute and arranged to act upon a continuous stream of water, all of which was subjected to the maximum and uniform action of the centrifugal force. This machine is more efficient than the filter paper, securing in some instances 98% of the planktonts. It is, however, subject to a selective error, in that the individuals and species whose specific gravity is the same as or less than that of the water are not removed by the action of the centrifugal force. Samples rich in water blooms proved to be most troublesome. *Anabœna* and *Clathrocystis*, as a rule, and many individuals of other genera, as *Euglena* and *Chlamydomonas*, readily pass through the machine. Water kept in the dark, or at low temperature, for some hours yields up such plankton more readily. The addition of alcohol to the water also facilitates precipitation. The most accurate results, however, were obtained after adding chloral hydrate to the water in quantities sufficient to kill the plankton. The selective character of this error, and its consequent uneven distribution in plankton varying greatly in the abundance of water blooms with the season and situation, render the use of the centrifuge of questionable utility as a basis for a complete analysis of the biologic contents of water.

The cylinders of the Berkefeld filter are made of 'infusorial earth' of such fineness as to remove effectually all solid matter from the water passing through them. The smallest cylinders were encased in a suitable mantle and attached to the centrifugal machine. The catch obtained in this manner contained from one-fourth to one-third more organisms than that of the filter paper, and was not subject to the irregularities resulting from the use of the centrifuge. This preliminary test was so promising that a larger form of the Berkefeld filter, known as an 'army filter, System Bruckner,' which has of late been introduced in the German and Austrian armies, was tried as a means of collecting plankton. It has the following advantages: its maximum capacity under favorable conditions is about two liters per minute; it is portable and can be used in the field; its simple construction favors the removal of the catch, and its capacity for filtration can be quickly renewed when it becomes clogged. At present it seems to offer the most effective method for the collection of the plankton which eludes the silk. It is, however, subject to one serious drawback; the removal of the catch from the filtering cylinder is accompanied by the addition of a considerable amount of the infusorial earth to the plankton. This renders the 'Danaid task' of counting doubly difficult and precludes volumetric determination. The desideratum for a filtering cylinder for this work is yet to be found. It should be an inexpensive porous earthenware cylinder whose outer surface is of sufficient fineness to preclude the penetration of minute organisms, and of a firmness sufficient to permit the removal of the catch with a stiff brush without disintegration. Experiments in this direction are now in progress.

This leakage of plankton through the silk is a matter of fundamental importance. A considerable volume of the contents of the water is lost at all seasons of the year, and in some instances the actual catch of the silk net is but a small fraction of the total plankton present. Filter-paper catches from a

variety of situations made at intervals throughout more than a year indicate that the silk net retains from one-half to one forty-fifth of the total solid contents of the water, the greater losses occurring from waters containing *Trachelomonas*, *Chlamydomonas*, *Euglena*, *Melosira* and other minute forms in abundance. The relative amount of silt is, however, much greater in the filter-paper catches than it is in those made with the silk, so that the actual volume of plankton lost is less than the above figures indicate. The amount escaping through the silk bears no constant relation to the amount retained. Under these conditions the volumetric determination of the plankton by the use of the silk net as a test of the productiveness of water is not only incomplete but may be misleading.

For the examination of the plankton by the statistical method the silk affords a satisfactory basis only for the larger forms, such as the *Entomostraca* and the larger *Rotifera* and *Protozoa*. For the smaller and often very abundant planktonts, such as *Melosira*, *Peridinium*, *Dinobryon*, *Raphidium*, *Scenedesmus Euglena*, *Trachelomonas* and *Chlamydomonas*, the Hensen method is wholly inadequate. For example, from water in which these smaller forms were not extremely abundant the silk retained organisms to the number of 248,200 per cubic meter, while the catch of the Berkefeld filter indicated the presence of 767,556,000 planktonts in the same amount of water. Many of the organisms listed in the counting tables of Apstein may in reality escape in large numbers through the silk. Thus, of *Codonella* as many as *twenty-one* individuals may escape to *one* retained. The Hensen method must be supplemented by a more accurate system of collection if a complete census of the water world is to be taken.

From the œcological point of view the plankton lost by leakage through the silk s of prime importance, for it is composed very largely of minute algæ, which constitute a fundamental link in the cycle of aquatic life. Any attempt to unravel the complex interrelation of the constituents of the plankton or to correlate its ever-progressing changes with the factors of its environment must be based upon reliable data. Biological theory and aquaculture alike demand improvement in the plankton method.

The errors enumerated above are doubtless exaggerated by the situation with which we deal—waters rich in plankton and more or less turbid with silt. The tests, however, cover a considerable seasonal and local range of quantity and constituency, and have been made in both clear and turbid waters. The plankton, moreover, is composed very largely of the same genera as those found in the lakes in which Apstein and Zacharias have carried on their investigations, and over 50% of the species are identical. The desirability of experiments in other waters is at least suggested.

SOUTHERN STAR-CLUSTERS.

THE last of the great contributions of Benjamin Apthorp Gould to astronomy is contained in the large volume recently published under the title *Cordoba Photographs: photographic observations of star-clusters from impressions made at the Argentine National Observatory*. This work gives the measurements of the relative positions of nine thousand stars included in thirty-five clusters of the southern heavens and in the Pleiades and Præsepe.

In addition to the other large enterprises which constituted the regular work of the Argentine Observatory, over twelve hundred plates of southern clusters were secured (no important one being omitted) in the decade beginning in 1872, of which 281 have been measured and 177 are now computed. Inasmuch as the dry plate pro-

cess was not available until more than one half of the plates had been secured (in 1881), the serious character of the task of merely obtaining the photographs, with all the difficulties of the wet process, is sufficiently apparent. But this labor was small relative to that of the subsequent measurements and computations, which were carried out rigorously in all respects during the past fifteen years. As for the work at the micrometer it is stated that two assistants, alternately measuring and recording, could ordinarily measure from thirty to thirty-five stars a day.

It is, indeed, unfortunate that it was necessary that so long a time should elapse before the publication of the results, for it has delayed the recognition of Dr. Gould's position as the leading pioneer in the application of photography to astronomy of precision. It should be recalled that it was necessary for him to solve for himself, or with the coöperation of his friend, Lewis M. Rutherfurd, most of the difficulties of adjustment, measurement and computation, which have since engaged the attention of frequent congresses of the committee of the *Carte celeste.* It was as early as 1866 that Dr. Gould presented to the National Academy his memoir on the reduction of photographic observations, with the determination of the position of thirty-nine stars in the Pleiades, from measures by Rutherfurd on plates he had taken. It is much to be regretted that the publication of this memoir did not occur until twenty years later.

On going to Cordoba in 1870 Dr. Gould carried with him the photographic object-glass which Rutherfurd had so successfully used, but to his dismay he found it had been broken on the voyage. Thus the work was delayed three years, although a hundred plates were obtained with the mended objective, then replaced by a new one. Two exposures, of about eight minutes, were made upon each plate, a slight shift in right ascension intervening, so that defects on the plates could be distinguished from stars; then a third exposure gave either a trail or one point of the trail before the star left the photographic field of view, whereby the orientation of the plate could be determined. Of course, great difficulty was found in securing accurately circular images, especially as the modern plan of a large guiding telescope was not employed, but 'plates not satisfactory in this respect were summarily rejected without hesitation, no record being made of them, or numbers assigned.'

The measurements were carried out with two micrometers constructed by Rutherfurd and used by him in his early work. The coordinates measured were position-angle and distance, referred to some selected star as center. In some cases, of large clusters, several centers were employed, but the final positions are in all cases reduced to differences of right ascension and declination ($\Delta\alpha$ and $\Delta\delta$) from a single central star. As each plate contained some stars whose position had been determined with a meridian circle, the comparison of the catalogue and photographic coordinates furnished equations of condition from which corrections were applied to the latter. The accordance of the separate determinations of $\Delta\alpha$ and $\Delta\delta$ on different plates is highly satisfactory, and is not exceeded in recent measurements of clusters by other astronomers provided with telescopes and measuring micrometers of the latest design. Were such confirmation longer necessary, the reliability of the photographic method would be sufficiently established by the results of this volume.

Dr. Gould expresses the 'fear that trustworthy inferences from stellar photographs may not be expected in the present condition of science and the photographic art,' and hence does not attempt to utilize the photographs for photometric purposes, although approximate magnitudes are as-

signed and discordances noted. It may be, however, that the plates will later prove more useful than was anticipated in this direction. Certainly a comparison would be interesting with the Harvard Arequipa plates, on which Bailey has detected numerous variable stars, and the periods of some might thereby be accurately fixed.

A chapter of the work, in parallel Spanish and English, is devoted to each cluster, furnishing all the necessary data of measurement, the relative positions, and comparison with other, visual, measures where existent. Excellent charts are given of all the clusters. At the time of the lamented death of Dr. Gould, a year ago, one-half (pp. 248) of the volume had been printed, and the computations of the remainder were practically complete. But the unfinished portion of the manuscript has been carefully prepared after the original plan by Mr. G. E. Whitaker, to whom Dr. Gould makes acknowledgment for ten years of efficient service, under the general supervision of Dr. S. C. Chandler, and the whole volume may be fairly 'regarded as coming complete from the hand of its author.'

CURRENT NOTES ON PHYSIOGRAPHY.

THE ASSAM EARTHQUAKE OF JUNE, 1897.

A REPORT on the earthquake of June 12, 1897, in the Province of Assam has lately been published by the government of India in the form of a number of letters from local officers, English and native. The shocks occurred in the Khasi hills, famous as the district of the heaviest known rainfall; they are ascribed to faulting, entirely independent of volcanic action, of which there was no trace. Many ancient monolithic monuments were broken, or even torn out of the earth; their previously undisturbed condition being taken as evidence that no such earthquake had visited the region since their erection. In many villages the heavier houses were thrown down or badly injured, and had not most of the inhabitants been out of doors after a rainy morning the loss of life would have reached a greater number than is now reported, 1542. Among the hills much damage was done by landslides occasioned by the shocks; hillside paths were thus carried away, villages destroyed, and many people killed in the valley fields. In the plains to the south many deep cracks and crater-like pits were opened. One of the cracks was a mile long, two or three feet wide and 16 feet deep. Two persons lost their lives by being engulfed in such cracks. The pits average six feet in diameter and are spread around with sand that was thrown out by jets of water. In the Sylhet plains, traversed by numerous water courses, most of the villages are on the belt of higher floodplain close to the streams, and there much loss was caused by the slipping of the banks into the channels. Cholera and fever followed the earthquake, by reason of the disarrangement of water supply and drainage.

THE MOODUS NOISES.

A CORRESPONDENT of the New York *Sun* states that the "famous and mysterious disturbances of the lower Connecticut valley, the 'Moodus noises,' are being heard again" after a silence of twelve years. The Indians knew of them before the coming of white men. For twenty years, up to 1729, the villagers thereabouts heard the noises almost continuously, 'shaking the houses and all there is in them.' They were again heard in 1852 and 1885. On the recent recurrence there was a sound like a clap of thunder, followed for some two hours by a roar like the echoes of a distant cataract. A day later there was a crashing sound like heavy muffled thunder, and a roar not unlike the wind in a tempest. The ground was shaken, causing houses to

tremble and crockery to rattle, 'as though in an earthquake.' In view of the compressed condition of the rocks in the Monson quarries, described by Niles some years ago, these indications of local disturbance are of much interest and deserve special study from local observers. The region is one of deformed crystalline rocks, but all the disturbances that can be dated geologically are of great antiquity. The nearest comparatively modern disturbances are in the Cretaceous and Tertiary strata of the islands south of New England.

PHYSIOGRAPHY OF MARYLAND.

THE first volume issued by the Maryland Geological Survey contains a sketch of the physiography of the State with hypsometric and geological maps. A good illustration of the natural use of the term 'plateau' as indicative of relative and not absolute altitude is found in its application to the Piedmont region, next inward from the coastal plain. Its highest part in Parrs ridge is under a thousand feet elevation. Sugarloaf mountain seems to be a well defined monadnock, surmounting the plateau. The major drainage of this region is in young valleys that show little relation to the underlying rocks; their streams give evidence of having been superposed through a cover of sedimentary strata which may have been the westward extension of the present costal plain, but "the broad fertile limestone valleys to which the present drainage has become partially adjusted are a striking feature of the area." We venture to express a hope that the fuller study of physiographic features promised for later volumes will not be addressed so much to 'those who may seek a home in Maryland' as to the teachers in the schools of the State, from whom the future citizens are to learn what the State really is.

TARR'S FIRST BOOK OF PHYSICAL GEOGRAPHY.

TARR's Elementary Physical Geography has been found too advanced by many teachers; hence a smaller book has been prepared. In most respects it presents a good view of the subject, especially where the treatment turns toward the geological side; but in a number of instances it fails to 'start at the beginning and make everything thoroughly clear.' There is not a clear recognition of what is essential and what is unessential in a physical geography. The astronomical pages contain a number of purely astronomical matters, valuable as general information but here occupying space that could be better used by expanding the description and explanation of strictly geographical topics. The treatment of light is too physical and too advanced for a First Book. The chapter on the earth's crust is avowedly geological, so much so that the beginner cannot really appreciate it. For the student of geography it is better not to cross these geological bridges until they are encountered on his geographical journey. Under the lands many good lessons are taught, but process receives relatively more attention than form; and in spite of the importance which process deserves, this seems a mistake in a book that should be essentially geographical.

There are a number of careless inaccuracies of statement. It is said of hurricanes that "their birthplace is near the tropics" (p. 116). "The north magnetic pole lies to the southwest of the true North Pole" (p. 54). The redundant 'this' is too common; for example, 'in lieu of this inability to really conceive this' (p. 27). The treatment of the tides is not lucid; two sentences beginning with 'therefore' are followed by a third, whose conclusion will leave still in the dark those teachers who are puzzled about what they call 'that tide on the other side of the earth.' In these latter respects the book bears too evident marks of hasty preparation.

HARVARD UNIVERSITY. W. M. DAVIS.

CURRENT NOTES ON ANTHROPOLOGY.

THE PAPUANS AND MELANESIANS.

In a short article in *Globus* (Bd. 72, No. 9) Professor F. Müller sets in sharp contrast from the linguistic side the Papuans and Melanesians. The latter he considers to be Malayo-Polynesians, deeply tinged with Papuan blood, and speaking languages which are Malayan in grammar, but with a vocabulary containing a considerable residuum of Papuan roots. They have a decimal system, while the Papuans have only two numerals; the Melanesian dialects all have pronomial suffixes, which are wholly unknown in Papuan tongues; and other equally marked differences.

Like the negroes of Africa, the Papuans have a large number of widely distinct linguistic stocks; while it is well known that the Melanesians and Malayo-Polynesians are monoglottic. Physically the Melanesians are almost identical with the Papuans, but their tongues prove the deep influence of other blood. The purest examples of the Papuans are to be found in the interior of New Guinea, where they occupy a vast territory of which we know scarcely anything.

In this connection should be mentioned a paper on 'Observations on a Collection of Papuan Crania,' by Dr. George A. Dorsey, with notes on their decorative features by Professor Wm. H. Holmes, lately published by the Field Museum, Chicago. The measurements are most carefully done.

ETHNOGRAPHY AND HISTORIC SCIENCE IN AMERICA.

Under the above title Dr. F. Ratzel has an article in the *Deutsche Zeitschrift für Geschichtswissenschaft*, 1897, No. 3, appreciative of several recent works by American historical writers. He points out with force how the study of the aboriginal population of America has widened the range of historical views among us in the last quarter of a century. "Prescott described ancient Mexico as a curiosity which might have belonged to another planet. To-day the pre-Columbian culture of America pours light on the historic consciousness of Americans. Far beyond colonial history stretches the indefinite expanse of aboriginal history. This close relationship of history and ethnography forces the problems of the histories of races and peoples on the attention of every historical student."

Just how that relationship is to be understood and brought into the writing of history is a question which is not yet fully answered, as is easily evident from Dr. Ratzel's paper and the appendix to it by Dr. K. Lamprecht, one of the editors of the *Zeitschrift*. Enough, however, that it is recognized by such high authorities as one which can no longer be neglected.

University of Pennsylvania.

BOTANICAL NOTES.

ENUMERATION OF THE PLANTS OF EUROPE.

Seven years ago (1890) Dr. K. Richter brought out the first volume of a work entitled 'Plantæ Europææ,' which was intended to enumerate all the flowering plants growing spontaneously in Europe. The death of the author brought the undertaking to a standstill, and threatened to leave the work unfinished and fragmentary. Fortunately this calamity has been averted, and we are likely to see the work completed within a few years. Dr. M. Gürke, of the Berlin Botanical Museum, has recently issued the first fascicle of the second volume, and a second fascicle is promised within a few months.

The original plan of the work, which is practically unchanged by the new editor, included the systematic arrangement of all the European species under their proper orders and classes. The first description of

each species was to be carefully cited, and a full list of synonyms given. The original author adhered to the 'law of priority' with considerable rigidity, and therefore cited the dates of the accepted specific names and all synonyms. His initial date for the present system of nomenclature was that of the publication of the first edition of Linnæus's 'Species Plantarum,' viz.: 1753, and he discarded absolutely all earlier names. Dr. Gürke apparently does not so fully sanction the strict application of the law of priority, although he follows it in nearly all cases, his practice agreeing with that of the other Berlin botanists, who would except certain long-used names from the application of the law.

Volume I. included the Monocotyledons, which number 1839 species, 840 sub-species, and 122 hybrids. These are divided among 259 genera. The largest orders are the Gramineæ (751 species), Liliaceæ (342), Cyperaceæ (287), Orchidaceæ (170), and Iridaceæ (105).

The first fascicle of Volume II. includes a number of orders of apetalous plants, arranged in the Engler and Prantl sequence, viz.: Juglandaceæ (1 species), Myricaceæ (2), Salicaceæ (234), Betulaceæ (24), Fagaceæ (34), Ulmaceæ (7), Moraceæ (22), Loranthaceæ (4), Santalaceæ (26), Balanophoraceæ (1), Aristolochiaceæ (16), Rafflesiaceæ (1), Polygonaceæ (138), and Chenopodiaceæ (unfinished, 89). In many of the foregoing orders the numbers include many hybrids. This is especially true of the Willows, of which there are 48 distinct species and more than three times as many hybrids (178); of the Oaks there are 21 species and 11 hybrids, but here there are included under the 21 species no less than 52 sub-species.

THE DISEASES OF BERMUDA LILIES.

THE beautiful lilies which are annually grown in enormous quantities, to be used for decorative purposes during the Easter services, have become seriously affected by some obscure diseases which threaten to drive out their cultivation. For some time Mr. A. F. Woods, the Assistant Chief of the Division of Vegetable Physiology and Pathology, in Washington, has been studying these diseases, in the hope of finding their cause and cure. The diseased condition is characterized by the spotting and distortion of the leaves, flowers and bulb-scales, and the stunting of the plants. In severe cases the leaves, as they appear above the ground, are marked with small, yellowish-white shrunken spots, which finally dry out and collapse. Occasionally the disease appears to be somewhat local, the leaves on one side of the stem, or of particular whorls, alone being affected. It is estimated that from twenty to sixty per cent. of the entire hot-house crop of these lilies is annually destroyed by disease.

Many theories have been suggested as to the cause of the trouble, some attributing it to the growth of the bulbs upon worn-out soils, some to the weakening of the vitality of the plants by unscientific treatment, as premature removal of leaves, premature harvesting of the bulbs and want of care in the selection of bulbs for propagation. Others again suggest that bad treatment of the bulbs in the forcing house is the principal cause, while still others think that insects produce the trouble.

Mr. Woods finds, upon investigation, that, instead of one disease, we have to deal with several. The lilies are suffering from a complication of diseases. He summarizes his results as follows: "The work done shows that the disease is due to a combination of causes. In the first place, the bulbs have become weakened through improper selection and improper propagation, and this weakening is further increased by the attacks of mites and certain fungi and bacteria. Bulbs which have

been weakened in this way might regain their strength if the mites and fungi could be kept down; but those which are naturally weak cannot be made strong. During the time plants are being forced they may also be weakened by overwatering and consequent asphyxiation of the roots, or by allowing the roots to become too dry and then overwatering. The foliage of such plants may be free from spots and distortions, but usually the leaves are badly diseased. The spotting and distortion of the foliage is often due to the direct attacks of several genera and species of aphides and of the young of the bulb mite; to the injection of water into the young leaves in watering or syringing, and to the presence of water between the young leaves of plants having soft foliage. The injuries from the attacks of organisms are always more severe in the susceptible or naturally weakened bulbs."

No single course of treatment can be recommended to help this trouble. Careful selection of the bulbs, rotation of crops, avoidance of premature cutting of the stems or digging of the bulbs, the use of aërated soil, care in watering, the careful destruction of aphides and mites and the use of chemical fertilizers, instead of those derived from animal excrement, are recommended as likely to materially check the disease.

University of Nebraska.

NOTES ON INORGANIC CHEMISTRY.

A recent number of the *Zeitschrift für anorganische Chemie* contains a review of the recent work on the genesis of petroleum and other natural hydrocarbons. Engler's hypothesis is that petroleum is formed by the distillation of animal fats at high pressure. Lobry de Bruyn has described a demonstration of this method of formation as a simple laboratory experiment. Heusler calls attention to the fact that Engler's distillate contains a considerable quantity of unsaturated hydrocarbons, which is not the case with petroleum. By treatment with aluminum chlorid these hydrocarbons are changed into a high-boiling lubricating oil; hence it is probable that petroleum formation took place in two stages, the first distillate being changed by metallic chlorids into petroleum. According to Ochsenius, petroleum was formed from plant and animal remains by heat and pressure under the influence of the salts derived from sea water. On the other hand, Moissan finds in his work on the metallic carbids, a confirmation of the theory first proposed by Mendeleef, that petroleum originates from the action of water on metallic carbids in the interior of the earth. Uranium carbid, for example, yields with water both solid and liquid hydrocarbons. These are, indeed, in part unsaturated, but at a higher temperature saturated hydrocarbons might be formed from them by the action of hydrogen, which is often evolved from carbids by water. Aluminum carbid and glucinum carbid, indeed, give with water pure methane (marsh gas). Viola believes that the asphalt and the petroleum of Castro de Volci, near Rome, in Eocene limestone and sandstone is of intratelluric origin, and has been distilled from great depths. The region shows decided evidence of volcanic phenomena. On the other hand, van Werweke holds that the petroleum of Pechelbronn, in Lower Alsace, has originated in Tertiary strata and has not come from below.

In a polemic article in the *Zeitschrift für angewandte Chemie*, D. Holde claims that the theory that petroleum has originated from animal remains should be known as the Engler-Höfer theory, Höfer having first proposed the theory in 1888 in his 'Das Erdöl und seine Verwandte,' and Engler having

by his experiments shown that petroleum can be thus formed.

FINALLY, Moissan, in the *Comptes Rendus*, states it as his opinion that according to its geological relations the formation of petroleum is to be ascribed to three different causes: (1) the decomposition of organic substances under the influence of pressure and heat; (2) the purely inorganic reaction between water and the metallic carbids; (3) volcanic processes. In many localities it is possible that all three of these factors may have contributed to the formation of petroleum.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

IN accordance with plans that we have already announced, the General Committee of the British Association for the Advancement of Science has decided that the next meeting will be at Bristol, under the presidency of Sir William Crookes.

SIR JOHN LUBBOCK has accepted the presidency of the International Congress of Zoology, which meets at Cambridge in August of next year. Sir William Flower was, as we regret to learn, compelled to resign the office, in view of the other pressing demands on his time and of medical advice.

PROFESSOR C. A. YOUNG, Professor A. A. Michelson and Professor E. S. Dana have been elected honorary members of the Philosophical Society of Cambridge University.

THE medals of the Royal Society will this year be awarded as follows: The Copley Medal to Professor Albert von Kölliker; a Royal Medal to Professor A. R. Forsyth; a Royal Medal to Sir Richard Strachey; the Davy Medal to J. H. Gladstone; and the Buchanan Medal to Sir John Simon.

SIR ROBERT BALL, President of the Royal Astronomical Society, has been presented with the Jubilee Medal.

DR. GEORGE H. HORN, the eminent entomologist, died at Philadelphia on November 25th. He was one of the Secretaries of the Philosophical Society and was formerly Corresponding Secretary of the Academy of Natural Sciences. He had been until recently professor in the University of Pennsylvania, though his connection with that institution was chiefly honorary. Dr. Horn was only fifty-eight years of age, and his death, following those of Cope and Allen, is a further severe loss to the city of Philadelphia and to science in America.

THE Rev. Dr. Samuel Houghton, from 1851 to 1881 professor of geology in Trinity College, Dublin, died on October 31st, aged seventy-six years. He was an original and versatile writer, having made many contributions not only to zoology and physiography, but also on medical subjects, including an elaborate work on the Principles of Animal Mechanics.

BY a private letter from Dr. J. Buttikofer we are informed that, although by the necessities of his recent appointment as Director of the Rotterdam Zoological Garden he has been obliged to leave Leyden Museum, where he has spent so many happy years, and which contains nearly all the zoological collections made by him in different countries of the world, he hopes, that as Leyden is distant but three-quarters of an hour from Rotterdam, to be able to do some ornithological work there. He is now engaged in finishing his report on the ornithological results of the Borneo Expedition, which he accompanied as zoologist, and of which some account was printed in SCIENCE of April 23, 1897.

PROFESSOR R. A. PHILIPPI, who, for forty-three years, has been Director of the National Museum in Santiago, Chile, having reached the age of ninety years, has resigned, and is succeeded by his son.

A MONUMENT to the eminent surgeon, the late Professor Billroth, was unveiled in Vienna on November 7th. Professor Gussenbaur, formerly assistant to Professor Billroth, made the principal address.

A BUST of Michael Faraday was unveiled at the Michael Faraday Board School, London, on November 15th. The bust, which is of white marble, was presented to the School by the managers of the Royal Institution of Great Britain, and is a copy of the original bust exe-

cuted by Matthew Noble. A brass tablet on the adjacent wall bears the following inscription: "Michael Faraday, natural philosopher, D.C.L., F.R.S., born at Newington, Surrey, September 22, 1791. He was a patient student, an eloquent expounder and a brilliant illustrator of the laws of nature. Fullerian Professor of Chemistry in the Royal Institution of Great Britain, 1833 to 1867. Faraday's noblest monument is his 'Experimental Researches in Electricity and Magnetism' from 1831 to 1851. He died at Hampton Court-green, August 25, 1867, and was interred in Highgate Cemetery."

LIEUTENANT PEARY sailed on the Lucania on November 27th and will lecture in Edinburgh, after which he will try to find in Scotland a vessel of from 300 to 500 tons register for his next expedition to the north.

THE steamship carrying the Belgian Antarctic Expedition has safely reached Rio Janeiro and left for Buenos Ayres on October 28th.

MM. RAOUL and Mary have returned to Paris from a governmental mission to make researches into the indigenous plants of the Malay peninsula, with a view to determine whether any of them are of use for pharmaceutical or commercial purposes.

PROFESSOR JADERIN, of Stockholm, has, according to the New York *Evening Post*, proposed to the Academy of Science of that city that it arrange with the government for a preliminary expedition, with Russia's cooperation, to go to Spitzbergen next summer, and there prepare for the final measurement of a degree of latitude in 1899 and 1900, with a view of obtaining more exact knowledge of the earth's form.

LIEUTENANT OLUFSEN, who returned last spring from Central Asia, will next year fit out a new expedition to the Pamir regions in order to make geographical and ethnographical explorations in the northern part of the Wakhan valley. The expenses of the expedition, which will last two years and include two scientific students, will be paid from the Carlsberg fund of the Danish government.

THE New York Park Board approved, on November 22d, the general plans of the zoological gardens in Bronx Park. There was no opposition to the plans at the public hearing.

THE Meteorological Institute of Berlin celebrated the fiftieth anniversary of its foundation on October 14th. Dr. von Bezold, Director, made an address, in which, according to *Die Natur*, he stated that the Institute had in North Germany 188 stations of the first class and nearly 2,000 smaller stations.

A SMALL marine laboratory, says *Nature*, was opened at Cullercoats on the 21st ult. by Principal Gurney, of the Durham College of Science, Newcastle-on-Tyne. The laboratory is the result of the public-spirited generosity of John Dent, Esq., the Vice-Chairman of the Committee. The laboratory was formally handed over to the Sea Fisheries Committee, to be worked in conjunction with the Durham College of Science, Mr. Meek being placed in charge of the scientific operations. A large company assembled, representing the Sea Fisheries Committee, the College of Science, the Natural History Society and the County Council.

THE Subtropical Laboratory of the United States Department of Agriculture, at Eustis, has been discontinued, but work will be done at Miami, Florida. Mr. Walter T. Swingle and Mr. H. J. Webber, who had charge of the laboratory at Eustis, are at present in Washington.

THE Smithsonian Institution has acquired the Hallett Phillips collection of Indian implements and antiquities from the Potomac valley.

MR. P. A. B. WIDENER, of Philadelphia, has given his residence on Broad street for a branch of the Free Library. The value of his gift is said to be one million dollars.

THE Annual Report of the British Board of Agriculture states that during the financial year 1896–7 the sum of £6,950 had been distributed to fourteen different educational institutions. The grant to the Durham College of Science was increased to £1,000, and that to Oxford University to £800. The Board recommends that a chair of agriculture and forestry be established at Cambridge University.

As the result of the preliminary examination made by Colonel Sir Thomas Holdich, the well-

known head of the Indian Survey Department, whose services were lent to the Ceylon government last winter by the government of India, a new survey is to be made of the island. The London *Times* states that the cadastral survey will be on a scale of 10 in. to the mile and the topographical on one of one in. to the mile. The triangulation and topographical survey will be completed in five or six years, but considerations of expense will cause the cadastral survey to be spread over a period of 25 years and to be restricted to crown lands and lands of doubtful ownership. The existing maps of Ceylon are full of errors, and for every grant made out of crown lands a special and expensive cadastral survey of the locality had to be executed.

THE Pirogof Museum of Surgery and Anatomy, in St. Petersburg, the plans for which we have already noted, was opened at the beginning of the present month. The building will serve not only as a museum, but also as the place of meeting of all the St. Petersburg medical societies. The $30,000 bequeathed for the purpose by Mme. Musin-Pushkin has been doubled by subscriptions, and some endowment remains after the cost of the building has been defrayed.

THE International Congress on the Protection of Birds, to which we have already called attention, opened at Aix-en-Provence on November 9th. The London *Times* states that the protection of insectivorous birds useful to agriculture was the chief matter discussed, and it was decided to forward to the governments of Europe, through the French Minister of Foreign Affairs, the resolutions that were formulated. Public educational bodies are also to be approached in order to obtain, if possible, the serious consideration of this important subject by schoolmasters and government school inspectors. Numerous French and Italian agricultural, horticultural and sporting societies were represented at the Congress, and delegates from the Selborne Society and the Society for the Protection of Birds were also present.

THE Civil Service Commission announces that on January 8, 1898, an examination will be held at Washington, D. C., and other places throughout the United States, for the position of Computer in the Nautical Almanac Office. Three vacancies are to be filled and only men are eligible.

THE University of Cambridge has after a long delay received $5,000 bequeathed by the late Dr. Joseph Gedge, who died in 1870 while with Sir Samuel Baker at Khartoum. The fund is for the establishment of a biennial prize for original research in physiology. It is open only to graduates of the University of more than five and less than seven years' standing.

DR. HUGHLINGS-JACKSON will give, on December 8th, the first lecture under the Jacksonian lectureship, established by the Neurological Society of London in his honor.

PROFESSOR OLIVER LODGE will deliver a course of six Christmas lectures (specially adapted to young people) on 'The Principles of the Electric Telegraph' at the Royal Institution, beginning on December 28th.

PROFESSOR ROYCE, of Harvard University, will deliver, at Cambridge, during the present year, six public lectures on 'Social Psychology.'

AT the meeting of the Botanical Club of the University of Chicago on November 23d Professor C. F. Millspaugh, Curator in Botany at the Field Columbian Museum, gave an account of his explorations in Yucatan, made on behalf of the Museum.

DR. H. C. PARKER gave, on November 29th, the first lecture in the course given annually by the New York Academy of Sciences. His subject was 'Recent Explorations in the Rocky Mountains of Canada,' including an account of the first ascent of Mount Lefroy, made by him last summer.

THE first of the Columbia University lectures in cooperation with the American Museum of Natural History will be given by Professor Kemp on Saturday, December 4th, and the two following Saturdays. The subject of his course is 'The Formation and Structures of the Crystalline Rocks.'

PROFESSOR GEORGE H. DARWIN, of Cambridge University, will lecture at Columbia University on the afternoon of December 10th,

nis subject being 'The History of the Earth and of the Moon.'

AT the last meeting of the Zoological Society of London it was reported that the additions to the Society's menagerie during the months of August, September and October were 435 in number, amongst which special attention was called to a male and two females of a large deer from the Altai Mountains, probably referable to *Cervus eustephanus*, and apparently different in species from any deer previously exhibited in the Society's gardens, and also to a young male of the Caucasian wild goat (*Capra caucasica*). The total number of visitors to the Society's gardens during the months of August, September and October was stated to have been 278,253, representing an increase of 55,283, as compared with the number for the same period in 1896. From this source alone an increase of £1,344 19s. had been received during the same period.

MR. L. O. HOWARD, of the Department of Agriculture, has been studying the work of the Massachusetts Gypsy Moth Commission in the neighborhood of Malden and Medford, with a view to the preparation of a special bulletin of the Division of Entomology, describing the process of extermination employed. Agent O. A. Hubbard, of the Committee, has been temporarily detached and detailed by the State Board of Agriculture to study the region infested by the brown-tail moth and warn property holders of the danger and the need of using active measures for its destruction.

MR. H. A. MORGAN gives, in Bulletin No. 48 of the Louisiana Agricultural Experiment Station, some interesting observations on *Trissolcus murgantiæ*, an important parasite in the eggs of the harlequin cabbage-bug in Louisiana. He finds that eggs of the cabbage-bug pierced by the parasite on July 20th produced adult parasites on July 30th, showing the entire life cycle of the parasite to be ten days. In August 60% of the eggs of the harlequin bug contained these parasites. Experiments are being conducted with a view to the introduction of this parasite into Kentucky and Ohio.

SINCE the *Medical News* was removed to New York, giving that city three of the four leading medical weeklies of America, the scientific and medical men of Philadelphia have felt the need of a good weekly journal. This will be filled after the first of January by the publication of the *Philadelphia Medical Journal*, to be edited by Dr. George M. Gould, and published by the Philadelphia Publishing Company, with a capital of $30,000, which we understand has been fully subscribed. The trustees consist of the leading physicians and medical professors of Philadelphia, the different schools being duly represented.

L'Intermediare des biologistes, the plans for which we announced sometime since, has now begun publication, the first number being dated November 5th. It will be published twice a month, and the present number contains twenty-four pages. In addition to an introduction we find a short article by M. Marey, advocating the plan brought forward by him at the recent meeting of the French Association in favor of an international control of physiological instruments; forty-six questions to which replies are requested; the contents of the special journals of zoology, botany, physiology and psychology and short descriptions of three instruments. The journal throughout shows the psychological interests of Professor Binet and his associates in the editorship. In the introduction it is stated that a complete bibliography of the literature, so far as it is contained in other journals, will be given, but we think that the magnitude of this undertaking is scarcely realized. The series of questions is a feature that has, perhaps, not been undertaken in a scientific journal and may prove of value. Among the 34 'collaborateurs' there are two Americans, Professors Minot and Baldwin, and one Englishman, Dr. Sherrington. The price of subscription for America is 12 fr., to be sent to the publishers, Schleicher Fréres, Paris.

THE last issue of *Industries and Iron* states that it is the first newspaper produced in Europe by the aid of the Lanston Monotype type-casting and composing machine. The whole of the matter in the body of the paper has been printed from types composed and justified into lines on the keyboard machine,

and the jacquard or perforated paper so produced has enabled the casting and setting into lines and galleys of the finished matter presented.

THE new rules of the United States Patent Office, which go into effect on January 1st, contain some important alterations. Hereafter no invention can be patented if it has been described two years or more before the filing of the application, or more than seven months after a foreign patent has been allowed. On the other hand, the duration of an American patent is not limited by its expiration in other countries.

THE South African Republic has passed an amendment to their patent laws which is an ingenious method of collecting revenue. Only a small fee is required for granting the patent, but for each period for which it is extended an additional payment is required. Thus, for example, from eleven years to the limit of fourteen years $1,000 is required.

A DEPUTATION from the Manchester Chamber of Commerce was received by the President of the British Board of Trade on November 17th, the object of which was to call attention to the fact that patent rights were granted to foreign subjects in Great Britain for inventions which cannot be patented in their own. It was stated that very serious injury was inflicted upon British industrial interests in consequence of this inequality, and it was asked that the Patents Act of 1883 should be amended so as to remove the inequality, and that the duration of any British patent granted to a foreigner should not exceed the term of his patent in his own country. The deputation also desired that, as complementary to this amendment, the British representative at the forthcoming congress of the international convention for the protection of industrial property, to be held in Brussels next month, should be instructed to support the propositions for the alteration of the rules of the convention, which would permit the amending legislation in question.

MR. CHARLES T. RITCHIE, President of the British Board of Trade, in a speech before the Croydon Chamber of Commerce on November 23d, is reported to have said that Great Britain had more to fear from the United States than from Germany in industrial competition. "The facts are serious," he continued, "and call upon us for the exercise of all our powers to enable us to maintain our position in the commercial world. There is no doubt the United States are executing orders which ought to be executed here. As we all know, an American firm obtained the contract for the Central Underground Railway (of London), as its bid was lower than those of the English concerns and it could deliver the supplies three months ahead of the British tenders. Many important Continental orders have gone to America. The same is to be said of Egypt and Japan, where the Americans are doing work that Englishmen should have done."

THE conductors of the London *Academy* have devised a successful plan of advertisement in selecting a British Academy of Letters and its forty 'Immortals.' With the exception of two or three superannuated giants and half-a-dozen contemporary men of letters, the list seems to be chiefly remarkable as an exhibition of the mediocrity of British literature. The only excuse for mentioning the proposed Academy in this place, however, is to call attention to the fact that it does not contain the name of a single man of science. It is probably true that there is now in Great Britain no man of science who is also a man of letters as Huxley was; still if philologists such as Professor Skeat and Professor Jebb, and historians such as Bishop Stubbs and the Rev. Dr. Gasquet, are included among the forty Olympians there seems to be no reason why men of science such as Lord Kelvin, Professor Foster, Professor Sidgwick and Mr. Galton should be excluded.

THE fiftieth anniversary of Professor Virchow's joining the teaching staff of Berlin University was celebrated on November 6th. The *Lancet* states that in 1847 Professor Virchow, who had previously belonged to the Army Medical Staff, was appointed a *privat-docent* at the University, but political considerations were all-powerful after the revolutionary troubles of 1848, and as he was known to hold democratic opinions he was under the necessity of leaving Berlin and accepting a professorship

at Würzburg, in Bavaria. His exile, however, did not last very long, for as far back as 1856 he was elected professor of pathological anatomy in Berlin, an appointment which he still retains. On account of Professor Virchow's infirm state of health the jubilee proceedings were of a more private character than would have otherwise been the case, being limited to addresses of congratulation delivered by the rector of the University and the dean and professor of the medical faculty. The rector, Professor Schmoller, referred to Professor Virchow's achievements not only as a physician and a pathologist, but also as a biologist and as a savant whose methods of research had influenced every branch of human knowledge. The dean, Professor Huebner, eulogized him as a *privat-docent* of an altogether superior order—a teacher not only of students, but also of professors. At an age when young men were, as a rule, far from having mastered what had been already discovered he succeeded in solving the most difficult problems of biology. Professor Virchow in his reply pointed out that he was happy in the knowledge that a body of men now existed in German universities strong enough not only to maintain the principles laid down by him, but also to continue the work in the light of modern developments. He felt that his work was done and that he was now entitled to retire from his academical position, especially after having succeeded in obtaining a promise from the government that a new and modern pathological institute and museum would be constructed after his designs. A great number of telegrams, letters and other marks of Professor Virchow's great popularity were received by him during the day.

THE National Photographic Record Association of Great Britain, to which we have already called attention, have sent out a circular in which they state that well-wishers of the Association, the subscription fee for which has been fixed at a small sum with the object of enlisting wide and general support. Photographers and others can assist by contributing photographs (which must comply with the regulations set forth in the by-laws), or by acting as honorary agents and collectors in their respective localities. The Council look for generous support from photographic and camera clubs throughout the country, as well as from individual amateur photographers, who must now form a complete network of workers over the whole British Islands. The Council also appeal to the large and important professional class of photographers for copies of rare and especially interesting pictures taken by them. From scientists, antiquarians and others assistance is desired in searching among the rich stores of old and neglected negatives taken in past years which are known to exist, the identification of which gets more difficult as time passes, and also by using influence with their amateur photographic friends in inducing them to seize opportunities of recording passing events. Others may render valuable help by purchasing pictures from dealers and presenting them to the national collection, thus rescuing records which might otherwise be lost. In the course of the present jubilee year there must have been many thousands of photographs taken of local celebrations, which, if brought together, would form a most valuable chapter of national history, and it may be remarked in passing that it should be born in mind that a single picture of historical interest will always be acceptable. In conclusion, the Council wish it to be understood that there is no thought of competing or clashing with the excellent work of the same kind which is being so well done by the several county photographic survey associations, such as those of Warwickshire, Worcestershire, Yorkshire, Cheshire, etc., in their commendable efforts to form local collections, but rather a hope is entertained that such useful work may be encouraged by loans being made from time to time from the national collection, before being deposited in the British Museum, of interesting pictures from other localities for the purposes of exhibition.

The Botanical Gazette states that the Seaboard Air Line Railroad, which extends from Portsmouth, Va., to Atlanta, Ga., has inaugurated a novel system of instruction of the communities along its territory. During the present season it has been holding one-day farmers' institutes, all illustrative material and appliances and the force of instructors being transported from place to place in a train of cars especially fitted up

for the work. It is proposed to establish experimental farms every ten miles along the whole line, twenty-eight having already been organized.

AT the first meeting of the present season of the Royal Geographical Society, the President, Sir Clements Markham, made an address in which he says, according to the report in the London *Times*, that the recess had been signalized by the publication of two important geographical works—the admirable monograph on British Central Africa, by Sir Harry Johnston, with its fascinating chapters on the scenery and the physical aspects of that region; and the 'First Crossing of Spitzbergen,' by Sir Martin Conway; while they had themselves brought out Sir William Macgregor's interesting paper on 'British New Guinea' in the form of a small volume. There had also been much activity in the field. In Africa, Mr. Cavendish, who only completed his twenty-first year last May, had made a very remarkable journey from Berbera, across the Somali country, to the river Jub, and then inland to Lake Rudolf. He shared with the late Captain Bòttego the honor of being the first to explore the western shores of that lake. With regard to Siam they might expect another communication from Mr. H. Warington Smyth. In Central Asia the labors of Dr. Sven Hedin, which had been continuous during several years, were of great geographical importance. Not less important and quite as interesting were the explorations now being carried on in the Afridi country by their gallant associate, Sir William Lockhart. They must all feel enthusiastic on reading of the skill and ability with which his old friend was conducting a most difficult campaign, and of the brilliant dash and devotion of the Gordon Highlanders and other troops who were serving under him. As Fellows of that Society they rejoiced that the success of their arms also entailed successes for the cause of geography. Their friend and associate, Mr. Fitzgerald, was also returning from his arduous examination of Aconcagua, which was believed to be the loftiest peak in the Chilian Andes. There would, so far as he was aware, be no new work from the Antarctic regions during the ensuing season, unless, as he hoped, the Belgian expedition, commanded by M. de Gerlache, should be able to send news of any discovery before the close of the season. But the efforts of their Council to procure the dispatch of a British Antarctic expedition had never ceased. Meanwhile, Sir George Newnes had supplied funds for a Norwegian enterprise, to be conducted by Herr Borchgrevink. In the Arctic regions there had been much activity this summer, and it was reported that it was the most open season that had been known for many years. They now had to welcome Mr. Jackson, Mr. Armitage, and the other members of the expedition on their safe return, and to congratulate Mr. Harmsworth on the valuable results of his patriotic munificence. Following the President's address, Mr. Frederick G. Jackson lectured on the scientific results of the Jackson-Harmsworth expedition.

AT the opening meeting of the Linnæan Society, London, an interesting collection of zoological and botanical exhibits collected by the Jackson-Harmsworth expedition was shown by Mr. F. G. Jackson, the leader, and Mr. Fisher, the botanist of the expedition, the former also exhibiting upon a screen a number of photographs of animals and birds which inhabit the Arctic regions. Some lantern slides of marsh birds and their nests from photographs recently taken in Spain and Holland were shown by Mr. Reginald Lodge. Following a discussion upon these exhibits, Sir John Lubbock, M. P., read a paper on 'The Attraction of Flowers for Insects,' in reply to three memoirs recently published by Professor Plateau. According to the report in the London *Times* Sir John Lubbock explained that his view was, like that of Sprengel and Darwin, that we owe to insects the beauty of our gardens and the sweetness of our fields. To them, he said, flowers were entitled for their scent and color. Not only had the present shapes and outlines, brilliant colors, the sweet scent and the honey of flowers been gradually developed through the unconscious selection exercised by insects, but this applied even to minor points, such as the arrangement of lines and the different shades of color.

UNIVERSITY AND EDUCATIONAL NEWS.

MR. THOMAS MCKEAN, of Philadelphia, has given $100,000 to the University of Pennsylvania for a building for the law school.

MR. JOHN D. ROCKFELLER, of New York, has given an additional $10,000 towards the erection of a hall at Mt. Holyoke College, and if the conditional gift of Dr. Pearson is included the sum of $175,000 has now been collected for the endowment fund.

BROWN UNIVERSITY has received $5,000 by the will of the late Eustace Fitz, of Chelsea, Mass.

FERRY HALL, one of the buildings of the State Agricultural College, Pullman, Washington, has been destroyed by fire, causing a loss of about $40,000.

THE registration in Harvard College is this year 1,814, an increase of 6.2 per cent. over last year. The number of students in the Lawrence Scientific School is 407, an increase of 9.5 per cent.

IT is stated that the decree excluding foreign students from the medical classes of the Faculty of Medicine of Paris will shortly be withdrawn.

DR. TH. CURTIUS, professor of chemistry at Bonn, has been called to Heidelberg as successor to Victor Meyer.

DISCUSSION AND CORRESPONDENCE.

HOTEL ACCOMMODATIONS AT ITHACA FOR MEMBERS OF THE SCIENTIFIC SOCIETIES.

SINCE the publication of the official announcement of the Society the Ithaca Hotel has been sold, and the new owners have closed it for extensive repairs. That hotel will not be open for guests nor for the annual dinner. The other hotels will be open. The Clinton House can accommodate from 50 to 75 and the new Hollister from 30 to 40 guests.

The annual dinner announced for the Ithaca Hotel will be held at the dining rooms in Cascadilla Place, these being the largest and pleasantest dining rooms upon the University campus in Ithaca. The time and cost will be as in the announcement.

A limited number of ladies can secure rooms and board at Sage College. Rates can be had upon application to the Local Secretary. There are numerous pleasant rooms in the near neighborhood of Cascadilla Place, which, with board in the house or at Cascadilla Place, would cost from 75 cts. to $1.50 per day. The Local Secretary will secure rooms for any who apply to him.

S. H. GAGE, *Chairman*,
W. W. ROWLEE, *Secretary*,
of the Local Committee.

ITHACA, N. Y.,
November 30, 1897.

THE CAIRN ON THE ENCHANTED MESA.

TO THE EDITOR OF SCIENCE: I have just read Professor Libbey's letter, in your issue of the 26th instant, in which he intimates that the lichen-covered cairn on the summit of the Enchanted Mesa was erected by himself. It now only remains for Professor Libbey to say that the ancient potsherds scattered through the talus, the artifacts found on the summit, the remains of the ancient ladder-trail and all the other evidences of the former occupancy of the summit of the mesa are the result of his own ingenuity. The last word will then have been said.

F. W. HODGE.

BUREAU OF AMERICAN ETHNOLOGY,
WASHINGTON, November 29, 1897.

[As Professor Libbey states that the cairn was erected by him Mr. Hodge should certainly correct his mistake. Whether or not the Mesa was formerly inhabited is another question.
ED. SCIENCE.

A POSSIBLE SOLUTION OF THE SEALING PROBLEM.

TO THE EDITOR OF SCIENCE: In the article in SCIENCE last week on the Sealing Conference, and in the innumerable articles that have been published since the question became prominent, I have not noticed any mention of what seems to an outsider the most natural solution. It is absurd for the United States to claim that it has any right to control the action of Canada on the high seas on the ground of humanity to animals or of commercial interests. Great

Britain would have just as much right to protest against the extermination, by the United States, of the buffalo and the beaver.

It has been suggested that the seals might be exterminated, but this would be sawing off the branch with the man on it, unless the proposers of this plan mean by it what I wish to suggest. This is that so many seals be killed on the Islands that there would not be enough left in the seas to make pelagic sealing profitable. It would seem possible to keep a small herd on the Islands and the killing of the small number would be very profitable, as the price of sealskins would doubtless rise. It looks to me as if we had the trump card in our hands and could offer Great Britain almost any conditions on pelagic sealing that we like.

P. C. H.

NEW YORK, November 27, 1897.

OBSERVATIONS ON THE PHYSIOGRAPHY OF WESTERN MASSACHUSETTS.

THE following notes on the character and elevation of the Cretaceous peneplain in western Massachussetts were made during a trip in the Berkshire region in the spring of 1897. The area covered lies between the Housatonic and Connecticut lowlands and south of the Boston and Albany Railroad.

From map-study alone the tendency is to locate the peneplain by the broadest tracts of level country to be found upon the map and to call what lies above monadnocks. It was found, however, that this estimate placed the peneplain altogether too low. The broad spaces proved on observation to be broad, shallow tracts of etched-out country, and most of what had been supposed from map-study to be monadnocks fell into a very good level skyline. The region contains but few monadnocks, and these of small size, their size and number decreasing from north to south.

In the township of Hinsdale the peneplain lies at a height of 2,050 to 2,100 feet; at Washington Centre it falls to 2,000 feet; and seven miles in a south-southeasterly direction, near Becket Centre, it is but 1,850 feet in height. Between Sandisfield Centre and New Marlborough, about seventeen miles due south of Washington, the height of the peneplain decreases to 1,750 feet; at Tolland Centre its elevation is about 1,550 feet; and at Blandford Centre, about eight miles to the northeast, the same. By comparison of these points the following conclusions were reached:

(1) The peneplain dips from about north-northwest to south-southeast.

(2) Its fall in twenty-five miles is about 550 feet, a rate of twenty-two feet to the mile.

An apparent consequence of this slope of the peneplain is the prevailingly south-southeast courses of the streams, great and small, throughout the area. Along the escarpments where the upland falls off into the Housatonic lowland or into the Connecticut lowland the streams naturally follow the steeper gradient and have cut east and west courses some distance back into the upland, though even these streams in their upper courses conform more and more to the habit of the other streams. The long axes of the lakes and ponds also lie prevailingly northwest and southeast, and the majority of the long, straight stretches of road follow the same direction.

ROLAND B. DIXON,
CHARLES D. DREW.

SCIENTIFIC LITERATURE.

The Dawn of Astronomy, a study of the temple-worship and mythology of the ancient Egyptians. By J. NORMAN LOCKYER. New York and London, The Macmillan Co. First edition, 1894; second edition, 1897. Octavo, pp. 432. Illustrated. Price, $3.

Sir Norman Lockyer first gave his attention to the questions treated in this book in the year 1890 and they are stated in his preface somewhat as follows: It is a matter of common knowledge that many of the churches of England are so constructed that their eastern windows face the point of sunrise on the day of the patron saint. For example, the churches dedicated to St. John the Baptist face nearly northeast. The question arises whether the Egyptian temples have a similar orientation to the sun or to some star. This can be completely determined by accurate surveys of the temple sites; by an investigation of the inscriptions, etc.; by a study of the mythology and history of the people; by the calcu-

lation of tables of the rising and setting of the stars for a period extending backward some 9,000 years, and by a painstaking discussion of the data so amassed. A part of the work described has been done by Professor Lockyer, and the results reached since the year 1890 (when some of them were first announced by him) are set forth in this volume. During visits to Egypt he executed surveys of a few temple-sites and the necessary calculations have since been made.

The French Scientific Commission which accompanied Napoleon in his Egyptian campaign, and the Commission sent by the Prussian government in 1844, have published a vast amount of accurate information regarding the sites, etc., of Egyptian monuments which bears directly on the problem in hand.

Professor Lockyer's general conclusion is that certain of the Egyptian temples are, in fact, oriented by the stars as well as others by the sun. The same conclusion was reached quite independently in 1885 by Professor Nissen, of Germany, though his work was unknown to Lockyer at the time. Such is the general problem. The particular developments are given in a stout octavo volume first printed in 1893 and now reprinted without change, I believe.

The course of the argument in detail is somewhat as follows: Egyptian chronology, the succession of kings, must be regarded as comparatively well known, considering the great difficulties of the subject. Making all allowances for errors, the dates of many temples are well fixed by their inscriptions. The mythology of Egypt has likewise been studied with remarkable success, and this mythology has, in general, astronomical relations, as indeed is the case in many countries. In Egypt, as in other lands, there were gods related to the sun, the moon, and a special goddess for the stars. Their zodiac is represented by existing sculptures whose figures have at once a mythologic and an astronomic meaning. The priests made sacrifices at dawn and at other seasons related to the sun's diurnal and annual courses. Inscriptions at Thebes show that the risings of stars were observed throughout the entire year; and the *heliacal* rising of Sirius was connected with the floods of the Nile. In Egypt, as in India, the pantheon was mainly composed of solar deities, but some of the personages had intimate relations to stars and planets.

During the course of the year the sun rises and sets at various points of the horizon of any place. It rises farther to the north during the summer, farther to the south during the winter season. A star, however, rises at (sensibly) the same point of the horizon for a century or so, though the stars, too, have a slow motion due to precession, which will, finally, produce great alterations in their points of rising. The rising of a star with the sun at a certain period of the year—its *heliacal* rising—would be a marked phenomenon, especially if the date coincided with a critical time of the agricultural cycle. Any recurring event of this nature may serve to mark off dates—the heliacal rising of a star; the rising (or setting) of the sun at the equinoxes or solstices; or the rising or setting of a fixed star. The orientation of a temple might well preserve the direction in which the semi-sacred appearance was visible and there is no doubt that many structures have been so oriented. From ancient times worshippers have chosen to face in a fixed direction during their devotion or sacrifice.

The existence of solar temples in many parts of the world is established beyond a doubt. Some Egyptian temples are oriented to the sun at its rising at the solstices (Karnak, Thebes, etc.); some to its rising at the equinoxes (Memphis, Gizeh, etc.) according to Professor Lockyer. The orientation is changed from solstitial to equinoctial in these cases, and Lockyer points out that so fundamental a variation in astronomical thought strongly suggests a change in the ruling race and religion. The rise of the Nile is related to the season of the summer solstice; that of the Tigris and Euphrates to the season of the spring equinox. Have we here, the author asks, an indication of two races which expressed ideas in the monuments? The suggestion is ingenious. So far as I know, it has not been very hospitably received by experts. It is interesting to note that the temple of the sun at Peking is oriented to the winter solstice; Stonehenge to the solstice of summer; the temple of Solomon similarly to the temple of Isis at the Pyramids;

St. Peter's at Rome so that the sun's rays at the vernal equinox illuminate the high altar, etc., according to Professor Lockyer. The inscriptions of some of the Egyptian temples prove, if proof is necessary, the intention of their builders. Speaking of a pair of obelisks at Karnak an inscription reads, "They are seen an endless number of miles away; it is a flood of shining splendor when the sun shines between the two;" and again, "The sun's disc shines between them as when it rises from the horizon of heaven."

It is to be noticed that if the orientations of the builders were exact, and if the measures and directions determined at the present day are accurate, it is a mere matter of calculation to fix the astronomical date at which a temple was constructed, provided their original intention is known to us. The dates of several of the solar temples can be assigned with considerable accuracy in this manner. If we should find, as in fact we do find, says Professor Lockyer, that the builders of set purpose have slightly altered the direction of the axis of a temple during its construction, this will be a sign to indicate that the celestial body related to the temple has changed its direction during the period, perhaps several centuries, of construction. It is upon facts of this kind that Lockyer bases his proof that some of the temples are related, not to the sun, but to stars. This is the key-note of the book. The change of direction of the axis is not to be explained by a change in the sun's direction, but demands another interpretation. The situations and arrangements of the principal stars were well known to the inhabitants of the Nile Valley. We have seen that many of the Egyptian temples are oriented to solar positions. There are many temples that cannot by any possibility be so oriented. They are built so that no ray of sunlight can pass along their axes at any period of the year. The question arises, are these temples oriented to stars? or, again, are they oriented at all? Are their directions assigned by chance? The topographic conditions of the sites seem to show, in a number of cases, that their builders had a set purpose in facing them as they are faced. If the direction of their walls had no significance they would, it seems, have been differently placed. The latter half of the volume under review is devoted to these questions, namely: Were such temples oriented to a star? to what star? and at what epoch were these monuments constructed?

Every detail of construction goes to show that this group of (stellar) temples was built to receive a horizontal ray of light along the axis just as the solar temples were. A striking fact in this connection is that the (stellar) temples frequently exhibit a change of direction of the principal axis, such as calculation shows would be necessary to allow for changes in the direction of stellar beams every few centuries. A solar temple does not require such changes of axial direction. "Once a solar temple, a solar temple for thousands of years; once a star temple, only *that* star temple for something like three hundred years." If after some three centuries the stellar light no longer penetrated the temple a change of direction of the axis would be required. It is just such changes of direction that have been found.

The foregoing summary is believed to represent with fairness the *method* adopted by Professor Lockyer, and to indicate, at least, his main conclusion, namely, that many of the Egyptian temples have stellar relations and were oriented so that the horizontal rays of Capella, *Gamma* Draconis, etc., etc., might fall along their axes at the time the buildings were constructed. The latter half of the book is given to a detailed proof of the stellar relations of the temples, and it deals not only with architectural measurements and astronomical computations, but with recondite questions of mythology, history and ethnology. To the writer of this review it seems that the chief merit of the book is to have called attention to a most important province of the history of the growth of astronomic notions (and thus of religious ideas) and to have set forth in plain and popular form the obvious method of research which must be resorted to. It seems that further research is called for. It may lead to certain and definite results. The present volume can hardly be said to have proved all its points. To judge it completely one should be historian, ethnologist and astronomer in one; but one need be no more than a

humble logician to point out various flaws in the argument.

I believe the Egyptologists do not accept the Zodiac of Denderah and the inferences of Biot as unreservedly as Professor Lockyer. The ethnologists will, I understand, raise many objections to Professor Lockyer's hypothesis of a change of race and religion. Mythologists will surely rebel against his treatment and interpretation of myths. Astronomers will point out how *many* stars there are and how few temples, so that it may not be so very difficult, given several hundred years of leeway, to choose a star to fit a temple. Plain people will ask how it is that a temple is, so to say, dedicated to one star and oriented by another. Sirius was the *star* related to Isis, Mut and Hathor. But the temples of these deities are not invariably oriented by Sirius. *Gamma* Draconis is a rather faint star. Why were not brighter ones selected?

After raising these objections and a crowd of others that might be brought forward, it remains that Professor Lockyer's book is a contribution of high value and merit. A question of importance has been plainly put. The method of solving it has been described in popular language. The data now available has been brought to the notice of everyone. If Professor Lockyer has done little more than this, and if his principal conclusions still call for further confirmation, he deserves the thanks of all concerned in these questions—and who is not?

EDWARD S. HOLDEN.

Song Birds and Water Fowl. By H. E. PARKHURST. New York, Scribners. October, 1897. Illustrated by Louis Agassiz Fuertes. 12mo, pp. 286. Price, $1.50.

If there is any truth in the law of supply and demand, the present flood of popular bird literature must be taken as evidence of an extraordinary if not unprecedented interest in the subject of birds and nature. It is a healthful interest and one which awakens and develops some of the better elements in our natures which are apt to lie dormant.

Mr. Parkhurst's 'Song Birds and Water Fowl' is not intended as an aid to the identification of specimens, but belongs rather to the class of popular nature studies. A fair idea of the contents may be had from the chapter headings, which are as follows: A Boquet of Song Birds; Water Fowl; A Bird's-Eye View; Mistress Cuckoo; Sea Swallows; Bird's Nests; At the Water's Edge; Lake George; A Colony of Herons; Earliest Signs of Spring.

The book is illustrated by eighteen admirable full-page drawings by Fuertes.

C. H. M.

Birdcraft, a Field Book of Two Hundred Song, Game, and Water Birds. By MABEL OSGOOD WRIGHT. New York, The Macmillan Co. November, 1897. With 80 full-page plates by Louis Agassiz Fuertes. 8mo, pp. 317. Price, $2.50.

The second edition of Mrs. Wright's 'Birdcraft' is a pleasant surprise. The cheap chromos of the first edition are replaced by a colored frontispiece and eighty full-page halftone plates from original drawings by Fuertes, the powerful young bird artist who has so suddenly sprung into fame. Most of these drawings have recently appeared in 'Citizen Bird,' by the same author and Dr. Elliott Coues (noticed in SCIENCE of November 5, 1897, p. 706).

Since the text of the second edition of 'Birdcraft' is printed in the main from the same electrotype plates as the first, it is only necessary to refer to the review of the former (SCIENCE, June 7, 1895, p. 635), with the additional statement that the principal errors there mentioned have been corrected. The book in its present form is attractive, interesting and helpful and should be in the library of every lover of birds.

C. H. M.

Magic Stage Illusions and Scientific Diversions, Including Trick Photography. Compiled and edited by ALBERT A. HOPKINS, with an introduction by HENRY RIDGELY EVANS. New York, Munn & Co. 1897. With four hundred illustrations. Large 8vo. Pp. 556. Price, $2.50.

The associations of the term magic are hardly suggestive of scientific processes or principles; they are more apt to call up an atmosphere of mystery and secret knowledge, a world of the

unexpected and the unfathomable. But the magic of to-day bears quite as conspicuously as many of the applied arts and crafts the marks of the laboratory and the research room. Nineteenth century magic reflects the evolution of nineteenth century science and can look back with an air of condescending amusement or curious interest upon its old-time antecedents, much as the modern chemist reads the annals of alchemy or the superbly equipped astronomer contemplates the vagaries of the medæival astrologer.

There is, indeed, much to interest the student of science in the elaborate performances of the prestidigitateur and the illusionist; and the interest is two-sided, physical and psychological.

The physical interest centers in the description of the true *modus operandi* of the tasks and the accompanying paraphernalia; the psychological interest in the method of arousing false perceptions and inferences and producing the conviction that the impossible has happened. The student of the psychology of deception takes his place with the audience and observes how readily their attention is diverted at critical moments, how easily they overlook the apparently insignificant but really essential settings of the trick, how the bewilderment increases and the critical faculties lapse as one bit of sleight-of-hand succeeds another. The student of the curious and intricate applications of science must be stationed behind the scenes and observe at times how simple a contrivance evades detection, or, again, how an elaborate combination of mechanical principles is ingeniously applied to produce a startling effect. The main lesson which the psychologist takes away is the importance of the attitude in creating belief, the dominance of cleverly suggested expectation in our sense experience, the readiness with which we substitute inference for observation and go away convinced and deceived. The physicist or the mechanician is quite certain to be impressed with manifold possibilities of mystification which the rapid increase of science brings in its train.

This ably compiled volume will appeal to both types of readers as well as to the more popular interest in mysteries and the processes of deception. It is wide in scope, treating of conjuring tricks of all varieties; of jugglers and fire-eaters; of puppets and shadow dances; of ventriloquism and second sight; of the application of science to stage effects and cycloramas and fireworks; of automatic and scientific toys; of the kinetoscope and the vitascope, and the varied applications of photography; and in addition to all this some interesting information upon the conjuring tricks and performances of olden times. The tone of the descriptions is clear and the volume is well adapted to satisfy the needs of the somewhat heterogeneous class of readers who are likely to consult it. Moreover, the book is distinctly modern, and avoids both the unnecessarily popular and frequently irrelevant style of much of this kind of literature. It comes as nearly within the pale of science as any book with this kind of a purpose can be expected to reach. A valuable bibliography and index add much to its usefulness.

JOSEPH JASTROW.

SOCIETIES AND ACADEMIES.

NEW YORK ACADEMY OF SCIENCES—SECTION OF BIOLOGY—NOVEMBER 8, 1897.

THE meeting was called to order by Professor Wilson, the Chairman. Twenty-two persons present. After reading the minutes of the previous meeting, the following program was presented:

Mr. Matthews reported on analyses of spermatozoa in Kossel's laboratory, Marburg. Sperm of *Arbacia*, herring, pig and bull were examined. Herring sperm heads were separated from the tails by Meischer's method, and made free from albumen. They consisted of protamin nucleate, having the formula $C_{40}H_{54}N_{14}P_4O_{27}$, $C_{30}H_{57}N_{17}O_6$. The nucleinic acid appeared identical with that of salmon sperm (Meischer), although the protamin differed from salmon protamin, as shown by Kossel. The sperm tails consisted chiefly of a combination of lecithin, cholesterin and albumen, similar to, but not identical with, similar constituents of salmon sperm tail. The tails contained no nuclein. The heads contained no lecithin nor cholesterin. *Arbacia* sperm contained nucleinic acid, but no protamin, instead of which a histon-like body was present. It is probable that *Arbacia* sperm chromatin is an histon nu-

cleate and more complex than fish-sperm chromatin. Neither bull or pig sperm contain protamin. The author suggests that the simplicity of fish-sperm chromatin is difficult to reconcile with Weismann's hypothesis.

Dr. Bashford Dean, in 'Notes on *Palæospondylus*,' gave a brief reply to Dr. Traquair's recent objections (Pro. Zool. Soc. Lond. March 16, 1897). The author notes:

(1) That the radial-shaped markings of the type specimen are certainly part of the fossil, since they occur in a second specimen now in the possession of Professor Stratford.

(2) That his broader interpretation of the 'unpaired nasal opening' (Traquair) as a naso-mouth ring (as in *Myxine*) was an independent as well as a necessary one, as will appear in the full paper.

(3) That the view of the presence of the radial-shaped markings as the probable supports of paired fins, the relations of *Palæospondylus* to the Marsipobranchs, become even more hypothetical.

Dr. Matthew reported on the status of the Puerco fauna. A review of the Puerco fauna, based on Dr. Wortman's geological observations in the field and the records kept by the American Museum collecting parties, shows that the Upper and Lower Puerco beds do not contain a species in common, and only three or four genera pass through. The two faunas are entirely distinct. Dr. Wortman proposes to call the upper beds the Torregon formation, retaining the name Puerco for the lower beds.

Mixodectes, formerly supposed to be a primate allied to the modern *Chiromys*, is a true Rodent in the first stage of evolution. It has the characteristic Rodent astragalus, very like that of the earlier Sciuromorphs. The incisor is intermediate between the short, rooted spatulate incisor of most modern mammals and the long, rootless scalpriform incisor of the Rodentia. The root is long, but does not grow from a persistent pulp, and the crown is long and pointed, but still retains much of the spatulate shape. The canine and anterior premolars are disappearing, the fourth premolar becoming molariform, and the molars showing some traces of an impending change to a type like that of the Wasatch rodents.

More complete material of many species shows that all the placental mammals were remarkably similar in skeleton structure. They were plantigrade, pentadactyl, with claws or narrow hoofs, short, clumsy limbs and long, heavy tail. Contrary to expectation, the podium and metapodium are not usually arranged in serial order. The carpus is alternating in the four species in which it is known, and the tarsus is serial in only two out of eleven species. Of these two, one is a primate, the other is the ancestor of *Phenacodus* and has an alternating carpus. The direct ancestors of the Perissodactyls and Artiodactyls do not seem to be among the known Basal Eocene species. The Creodont *Clænodon* resembles the modern bears in foot structure as well as in the teeth, and may have been ancestral to them. Considering that such widely different types as the Edentates, Rodents, Primates and Amblypods have been traced to their first beginnings in the Basal Eocene, it may be concluded that the first differentiation of all the Placental mammals took place at the beginning of the Tertiary and not in the Cretaceous as has frequently been stated. Dr. Matthews' paper was discussed at length by Professor Osborn and Dr. Wortman.

Mr. Harrington reported on some observations which he had made on 'Earth Worms during Copulation.' He described an organ which apparently had been usually overlooked. This organ, the spermatophore of some authors, consists of a modified seta, much enlarged at the extremity and functioning, as Mr. Harrington suggests, to force spermatozoa into the seminal receptacles of the other worm.

GARY N. CALKINS,
Secretary of Section.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of St. Louis on the evening of November 15, 1897, Professor F. E. Nipher presented informally some of the results of recent experiments on the stability of a pivotally mounted sheet in an air stream, his experiments having been performed by exposing the pressure planes on the roof of a moving box car.

WILLIAM TRELEASE.
Secretary.

*THE REVIVAL OF ALCHEMY.**

"Superfluous rehearsalls I lay asyde,
Intendyng only to give trew informatyon
Both of the theoryke and practicall
operatyon;
That by my wrytyng who so will
guyded be,
Of hys intente perfyctly speed thall he."
GEORGE RIPLEY (1471).

FRAUD, folly and failure have been deeply written into the annals of alchemy in all ages; it was early characterized as an 'art without art, beginning with deceit, continued by labor and ending in poverty,' and in modern times its extravagant pretensions have been condemned by an exact and critical science, yet notwithstanding there are to-day indications of a resuscitation of the captivating theories and of renewed attempts at their practical application, of great interest to students of the intellectual vagaries of mankind.

Belief in the possibilility of prolonging life by an artificial elixir and of transmuting base metals into silver and gold was generally entertained in the Middle Ages, not only by the ignorant masses, but even by serious-minded philosophers imbued with all the learning of the time; and the popular faith was sustained by the tricks of unprincipled impostors who found it profitable to prey upon the credulity and avarice of their fellow men. Those who in

* Read before the New York Section of the American Chemical Society, October 1, 1897.

modern times have written of alchemists find in the extravagant views of a Paracelsus, and in the careers of a Flamel, a Sendivogius, or of a John Dee, more entertaining materials than in the abstract conceptions of sober philosophers, and consequently most readers are more familiar with the misdeeds of adventurers than with the honest beliefs of respectable men of science. Before condemning those who labored day and night to solve the problems of transmutation and the elixir of life we should consider their intellectual environment; superstitious beliefs of every kind prevailed; even the sciences were in bondage; astronomy was dominated by astrology; medicine was influenced by magic; natural history was subject to blind belief in authorities, and scientific chemistry was entirely overwhelmed by the chimeras of alchemy. Kepler and Tycho Brahe, at the Court of Rudolph II., did not think it beneath their dignity to cast horoscopes for gain and to predict the future by consulting the positions of celestial bodies, even while formulating the laws governing their motions. European crowned heads retained astrologers and alchemists as members of their courts. A century later Sir Isaac Newton dabbled with furnaces and chemicals in true hermetic style; and Leibnitz showed the courage of his convictions by acting as Secretary of an Alchemical Society in Germany. The influence of superstition on the mental attitude of truly great men decreased with the advancement of learning, and when the foundations of scientific chemistry were laid by Priestley, Lavoisier, Scheele and their contemporaries, the doctrines of alchemy were abandoned. And yet not wholly abandoned, for there seems to have been a small number of persons in all countries who have clung to the hope of realizing transmutation, a hope sustained by the desire to reap the golden reward. This minority rejected the extravagant belief in a life-prolonging elixir, and in the divine origin of the profound secrets of the initiated, and sought to appropriate from the growing sciences such discoveries and theories as could be interpreted in favor of transmutation.

The printing press has never ceased to issue works devoted to the subject. Some authors have written of a 'higher chemistry,' and others have sought to reconcile the new doctrines of chemists with the ancient theories of alchemists. As recently as 1832 a German professor wrote a learned volume with the avowed intent of proving the verity of transmutation from historical sources (*Schmieder's Geschichte der Alchemie, Halle,* 1832). The number of reprints of the grotesque writings of reputed adepts which have appeared since chemistry has become an exact science is surprisingly large, and the fact that they find purchasers indicates a small but zealous class of hermetic students. So eminent a chemist as Sir Humphry Davy did not hesitate to affirm that some of the doctrines of alchemy are not unphilosophical.

Recent discoveries in physics, chemistry and psychology have given the disciples of Hermes renewed hopes, and the present position of chemical philosophy has given the fundamental doctrine of alchemy a substantial impetus; the favorite theory of a *prima materia*, or primary matter, the basis of all the elementary bodies, has received new support by the discoveries of allotropism of the elements, isomerism of organic compounds, the revelations of the spectroscope, the practical demonstrations by Norman Lockyer, the experiments on the specific heat of gaseous bodies at a high temperature by Mallard and Le Châtelier, the discoveries of Sir William Crookes as set forth in his monograph on 'Meta-elements,' the discovery by Carey Lea of several singular allotropic forms of silver, and, most

weighty of all, the mass of related facts and phenomena which find their ultimate expression in the Periodic Law of the Elements, so that many chemists of the present day are inclined to believe in the mutual convertibility of elements having similar chemical properties. Daniel Berthelot, in his notable work entitled 'De l' allotropie des corps simples,' boldly affirms his belief in the unity of matter. He says: "Without seeking to find in any one of the known elements the generator of the others, can we not invoke the facts that we have revealed in our study of carbon, in favor of the hypothesis of a unique matter unequally condensed?" And elsewhere he writes: "The transmutation of an element is nothing more than the transformation of the motions which determine the existence of said element, and which gives it special properties, into the specific motions peculiar to the existence of another element."

Simultaneously with the development of the truly scientific aspect of alchemical theory, there has arisen an extraordinary revival of the metaphysical side of the question; this goes hand in hand with the interest in chiromancy, astrology, theosophy and occult sciences which occupy so large a place in modern thought, literature and polite society on both sides of the Atlantic. This tendency to cultivate the esoteric manifests itself in the study of the Kabala, the investigation of the mysteries of Buddhism, Confucianism and other oriental philosophies, in researches into the phenomena of spiritualism so-called, and in the foundation of societies to study Psychic Force and the tenets of the followers of Madame Blavatsky; crystal-gazing, reading in magic mirrors, slate-writing, planchette, the quasi-scientific study of apparitions, of table-turnings, of rappings by unseen powers, of telepathy, of subliminal self, are now regarded as legitimate pursuits in no wise necessarily associated with the black arts of mediæval times, provided only they are conducted in a spirit of enquiry and for the purpose of discovering the latent power underlying these phenomena. And this line of research receives stimulus from the results secured by students of experimental psychology, of hypnotism, from such discoveries as the phenomena of the X-rays, and from the transcendental physicists who theorize on the miraculous consequences of four dimensional matter. Crowded lecture halls reward exhibitions of trance mediums, speakers on theosophy, palmistry and occultism; in lower walks of life fortune-tellers and clairvoyants reap a modest harvest; books treating of occult themes enjoy great notoriety; writers of fiction find it profitable to introduce the mysterious into the children of their brains; even secular journals, especially those of France, give space to the all-absorbing discussions on hermetism; these are some of the evidences of great popular interest in the unknowable. Only persons with special intellectual equipment are able to measure, weigh, sift and coordinate the novel phenomena gathered by researches in the field of hypnotism, psychology and occultism; those of weaker mental powers fail to perceive the real significance of the discoveries and are led away into unprofitable and dangerous superstitions.

In the Middle Ages alchemy was nurtured by ignorant superstition; now it is fostered by the prevalent devotion to esoteric studies; formerly the popular belief was in part supported by the fraudulent claims of impostors; now a higher standard of intelligence rejects the transparent tricks of imitators of Cagliostro. There are, indeed, occasional attempts to swindle the credulous by appeals to avarice; we read in the daily press of an American confidence-man who tried to cheat a London jeweler by pretending to 'multiply' sovereigns; of a

vulgar scheme of fraud among ignorant tradesmen on the east side of New York City, in which lead, iron scraps, crucibles and furnaces formed the properties; and of the larger operations of an educated French chemist who found dupes in both South and North America; but in each of these cases the severe logic of law courts intervened and abruptly discomfited the swindlers. It is not by sleight-of-hand that the revival of alchemy is now being engineered, but by a company of educated charlatans.

The movement to resuscitate alchemical doctrines and practices has been particularly successful in France, where there are to-day four societies and a 'university' claiming to possess occult knowledge of hermetic mysteries; these secret societies are named: 'Ordre de la Rose-Croix, 'L'Ordre Martiniste,' 'La Société d' Homéopathie Hermétique' and 'L' Association Alchimique de France.'

The first two of these societies seem to work on lines similar to Free Masonry, and claim that their secret mysteries were bequeathed by the last sages of Atlantis and by the Lemures to their brethren in Asia and Egypt, dwellers in sanctuaries whence issued Krishna, Zoroaster, Hermes, Moses, Pythagoras and Plato. The priestly Magi who preserved this lore in the temples of Thebes, Heracleopolis, Aphrodite, Pthah and Serapis were succeeded by secret alchemical societies of the first centuries of our era; then followed the Hermetic lodges of the Arabs, and these gave rise to the Templars, the Rosicrucians and the Martinists.

The third society cultivates especially occult therapeutics, a system of medicine invented in the sixties by Count Cæsar Mattei, of Bologna, which unites the principles of Hahnemann with those of the Iatro-chemists, disciples of Paracelsus. This new departure in medicine publishes four monthly organs and special treatises all its own.

The Alchemical Association of France is successor to the Société Hermétique, which was founded by the late Albert Poisson († 1894), also known by the pen-name *Philophotes.* Its seat is in Paris; the objects of the Association as set forth in its Constitution are "the theoretical and experimental study of evolution and of the transmutation of bodies. Its members, with this end in view, study the processes of the ancient alchemists and compare them with the work of modern chemists." These objects are to be accomplished as follows: "The Association proposes to assist in reviving the unitary doctrines of chemistry: 1st, by grouping the efforts of isolated workers by means of *L'Hyperchimie;* 2d, by furnishing them the aid of advanced students; 3d, by supplying so far as possible books and apparatus to its members. Researches of the members, when approved by the Masters, should be forwarded in duplicate to the Secretary-General; one will be printed in *L'Hyperchimie*, and the other will be preserved in the archives of the Association for the benefit of members who can secure it on demand." "Candidates for admission must pass an examination in: 1st, the theory and history of alchemy; and 2d, the elements of physics and of chemistry (without mathematics). A diploma from a normal, polytechnic or industrial school will be accepted in place of No. 2."

The affairs of the Association are controlled by the Secretary-General, F. Jollivet-Castelot (of Douai), assisted by seven Councillors, who hold an annual meeting. There are at present (July, 1897) two Honorary Members, Camille Flammarion, the popular writer on astronomy, and August Strindberg, a Swede residing in Austria, author of several hermetic essays.* There are two other classes of members,

* Dr. Stephen H. Emmens, of New York, has been added to the list of honorary members since writing the above.

masters (*maîtres*), who are chosen from the ordinary members by the Council after an examination of their writings; and ordinary members (*membres adhérents*), of which the number is unlimited. Modest dues entitle the members to the organ of the Association, *L'Hyperchimie*, a monthly review of alchemy and hermetism founded in 1896.

The Councillors of the Alchemical Association have combined with the active members of the other Societies named to establish a *Université Libre des Hautes Études*. At present this includes three Faculties:

I. Faculté des Sciences Hermétiques, of which the Association Alchimique forms a section. The director of this Faculty is Dr. G. Encausse, and the course of instruction embraces the study of the *Tarot*, alchemical philosophy and practice, occultism, mysticism, Hebrew, etc.; the curriculum leading to the 'baccalauréat-en-Kabbale' is under the supervision of the Group of Esoteric Students, while candidates for the degrees of master and doctor are under the direction of the Martinist Order.

II. Faculté des Sciences Magnétiques, represented by the École de Magnétisme de Paris, and under the direction of M. Durville; it has branches at Lyons, Bordeaux and other cities.

III. Faculté Spirite, comprising several sections of Spiritism.

Each Faculty preserves complete independence, being 'united only by moral bonds destined to hasten expansion of the rational spiritualistic movement.'

The nature of the instruction given at this University will appear in the review of the philosophy of its promoters.

The leading spirits in these secret societies and in this University are as follows: F. Jollivet-Castelot, Secretary-General of the Alchemical Association, special delegate to the Supreme Council of the Martinists, editor of *L'Hyperchimie*, and author of 'Comment on devient Alchimiste,' 'L'Hylozoisme' and other alchemic treatises; Dr. M. H. E. Lalande, whose pen-name is *Marc Haven*; F. Ch. Barlet, author of 'Essai sur l'Evolution de l'Idée;' Dr. G. Encausse, who generally conceals his identity under the signature *Papus*, is President of the Esoteric Group,* President of the Supreme Council of the Martinists and the author of sixteen treatises on hermetism and magic, among which may be named 'Traité élémentaire de Magie Pratique.' Papus is also editor of *L'Initiation*, a journal devoted to theosophy, magic and occultism, and of *Le Voile d'Isis* a weekly review of spiritualism. Stanislas de Guaita is best known as the author of 'Le Temple de Satan,' 'Clef de la Magie Noire,' and 'Le Probleme du Mal,' works dealing with sorcery, the astral light in man and other mysteries. Marius Decrespe's essay on 'Les Microbes de l'Astral,' Paul Sédir's 'Les Incantations' and Albert de Rocha's 'Exteriorisation de la Motricité' are works which indicate the mental attitude of those engaged in the revival of alchemy and hermetism. A bibliography of this class of works is here out of place; a single trade catalogue enumerates one hundred and twenty titles, chiefly of recent date.

One of the oldest workers in the Alchemical Association is the 'Master' Théodore Tiffereau; in 1854–55 he sent to the French Academy of Sciences six memoirs in which he claimed to have discovered a method of converting silver into gold. Tiffereau had made his experiments in Mexico at great expense, supporting himself meanwhile by taking daguerreotypes. His process was repeated at the Mint in Paris before the as-

* The Groupe Indépendant d'Études Ésotériques has 1,600 members, 104 branches and correspondents. It embraces members of the following societies: Ordre Martiniste, Ordre Kabbalistique de la Rose-Croix, Église Gnostique, Société Alchimique de France. Membership is free.

sayer, M. Levol, but with little success. The substance of his memoirs was published in 1855 in a volume entitled 'Les Métaux sont des Corps Composés;' of this a new edition was published by Lermina in 1889. Tiffereau has never abandoned his claim, and as recently as October, 1896, he addressed another memoir to the Academy, in which he attempts to prove that the metal aluminum is a compound. Briefly stated his process is as follows: He placed in a stout glass tube a piece of aluminum foil with pure nitric acid and sealed the tube hermetically. He then exposed the tube and contents to the sun's rays during two months; at the end of this time he opened the tube; it gave out an odor which he thought was due to ether, and it yielded a few grammes of crystals which he thought tasted like acetic acid. Since both ether and acetic acid are compounds of carbon, Tiffereau concluded that this element was derived from the aluminum. Analytical chemists would criticize this experiment in several points; they would say Tiffereau did not demonstrate the absence of carbon in the metal used, and that he depended upon smell and taste for proofs of the carbon compounds; the tongue and the nose are incontestably useful adjuncts to the reagents of a chemical laboratory, but additional tests for ether and acetic acid would have been more conclusive. In Tiffereau's recent writings he attributes the transmutation of a base metal into the most precious one, to the action of the 'microbe of gold.'

For a student of chemistry to read, digest and write down in intelligible language, in a limited space, the principles of this new school of chemical philosophers is a difficult task, even for one somewhat familiar with the literature of the ancient alchemists; consequently the following analysis falls far short of the ideal. It is properly the work of a kabalist, a theosophist and a magician, proud designations which the writer disclaims. The modern alchemists accept all the traditions of their ancient predecessors, but give them a new significance, and interweave the novel phenomena derived from researches in pure science. They claim that during the fourteenth, fifteenth and sixteenth centuries the official schools of instruction taught exclusively the physical part of the sciences, and that the metaphysical part (which is the real life and soul of the study) has been rejected under the opprobrious name of occult science. This living aspect of science has, however, been studied in the secret societies of the initiated, which have preserved the traditions of the kabala, the mysteries of hermetism and the practice of transmutation. The study of science is as much a religious question as an intellectual one, and worship at an altar should sustain and enlighten the worker in a laboratory. 'Chemistry, alchemy and hermetic philosophy form three steps of the ladder which leads the initiated from the laboratory, through artistic realization, to the oratory: '*Labora, Opera, Ora et Invenies.*' "

The modern alchemists also maintain that Darwin and his disciples appreciated but a small part of the great doctrine of evolution, which should be applied to the chemical elements as well as to living beings. The starting point in the evolution of elements is the ether (the universal astral fluid of the kabalists), the infinitely divisible particles of which form chemical atoms by agglomeration. This ether is condensed energy, and hence all matter is resolved into energy.

Energy, matter and motion form a trinity analogous to the Divine Trinity, one in substance, three in appearance. Matter is one in kind, and the diversity of chemical bodies results from differences in grouping and in motions of the constituent particles. Intelligence is allied in a mysterious way

with matter and energy, forming another trinity. Every atom centralizes intelligence, is in itself a living entity and by a process of self-evolution yields the diverse natural bodies. "Ether is the father of hydrogen, from which are derived oxygen, nitrogen, carbon, etc., combinations due to etheric vortices." "Perhaps helium should precede hydrogen." This view of matter as a living entity is greatly insisted on, and the doctrine is called *Hylozoism.* An alchemist who expects to succeed must possess psychic power over the atoms, so that by the action of his will they shall group themselves to form the metal desired.

Such is the physical philosophy of modern alchemists; the kabalistic philosophy is by no means so clear, being closely linked to the *Tarot*, which signifies the 'hieroglyphs and algebraic calculations of the Primordial Genesis.'

Students of the mystical philosophy of the Hebrews discover profound occult significance in accidental similarities of widely differing objects and phenomena. The seven planets, seven days of the week, seven colors, seven orifices in the head, seven metals known to the ancients, seven archangels and seven infernal demons present to the truly kabalistic mind marvellous and precious analogies. In the 'Table of Concordance of Major Arcana' these correspondences are given: 'Heth–Justice–Elementary existence–Nizah–Cancer–June–Hydrogen–Fire.'

Jollivet-Castelot has written of Kabalistic Alchemy, and a perusal of his essays leaves in the mind of the uninitiated confused memories of colors, numbers, signs of the zodiac, alchemical operations as distillation, fixation and the like, the names of the sons of Jacob, certain precious stones, geometrical figures, Hebrew characters, Azoth, quintessence and the Devil, all discussed in a language as obscure as the symbolism portrayed. To conceal esoteric mysteries abbreviations are often used, but one does not have to be very deeply initiated to recognize in P.·. Ph.·. 'pierre philosophale,' and in G.·. O.·. 'grand oeuvre.'

Astral light is an important factor in modern hermetism, and is related very closely to the 'radiant matter' of chemists and the 'ether' of physicists. "Astral light is the universal agent, the universal plastic mediator, the common receptacle of vibrations of motion and of the phantoms of form." It is also the Od of the Hebrews and of Baron von Reichenbach; it is the great Thelesma of Hermes Trismegistus, and the control of this force constitutes the great arcana of practical magic. It heats, illuminates, magnetizes, attracts, repels, vivifies, destroys, coagulates, separates, crushes and gathers all things under the stimulus of powerful wills; it is a perpetual and transformable vibration. Its kabalistic figure, represented by the Serpent of Theogonies, is:

$$\begin{aligned} \text{Od} &= + \\ \text{Ob} &= - \\ \text{Aour} &= \infty \end{aligned}$$

When the universal light magnetizes the universe it is called astral light; when it forms metals it is called *Azoth*, or the Mercury of the Sages; when it gives light to animals it is called animal magnetism. The astral undulations determine the position of the atoms or neutralize them. Herein lies the secret of transmutation, and it becomes the privilege of the hermetist to acquire the power of controlling this agent.

The adepts in this phase of hermetism still appeal to the *Tabula Smaragdina* of Hermes Trismegistus as the embodiment of alchemic lore. The 'Father of Alchemy,' who has been identified with Canaan, Noah's grandson, invented arithmetic, geometry, astronomy and music, taught writing to the Egyptians, and gave laws and religious rites to the people; he was

perfectly acquainted with the 'philosophers' stone,' and, desirous that posterity should inherit the wonderful secret, he had the whole art of creating gold engraved on an emerald tablet, which was placed in his sepulchre. Many years later this was removed by Sarah, Abraham's wife, and she concealed it in a cave near Hebron; there it remained until again discovered by Alexander the Great. The inscription reads in part as follows:

"I speak not of fictitious things, but of that which is most true and certain. Whatsoever is below is like that which is above, and that which is above is like that which is below, to accomplish the miracles of one thing. Also since all things were made from one by the help of one, so all things are made from one thing by conjunction. The Father thereof is the Sun and the Mother thereof is the Moon; the wind carries it in his belly, and the nurse thereof is the earth. * * * This thing has more fortitude than fortitude itself, because it will overcome every subtile thing and penetrate every solid thing. By it this world was formed. Hence proceed wonderful things which in this wise were established. For this reason I am called Hermes Trismegistus, because I possess three parts of the philosophy of the whole world. What I had to say about the work of the sun is completed."

Writers on modern alchemy discuss the marvels of palingenesis, of homunculi, and of gamahes; they write of the materialization of a metal through the medium (mediumnité) of a metal; they cite the 'Rules of Philalethes,' the works of George Ripley and of the Cosmopolite, and refer in the same essay to Berzelius, Berthelot and Moissan. We are told that "*le diable est le singe de Dieu*," and that the "Cherubim of the Ark of the Covenant symbolizes the male and the female of the Universe, the Alchemical Father and Mother," by the very authors who show acquaintance with the most recent advances in pure chemistry. In liquid fluorin they perceive a realization of the Alkahest, or universal solvent long sought by mediæval alchemists.

Accustomed to juggle with numbers, the kabalist finds abundant opportunity in the atomic weights of the elements, and he makes the most of his opportunity. When the arithmetical sum of the atomic weights of elements entering into a given compound chances to equal the atomic weight of gold, this accidental correspondence is seized upon as a pretext for claiming hermetic relationship between the two substances.

August Strindberg has devoted much study to such correspondence and points out the following:

$$K_2MnO_4 = 197 = Au$$
$$Cu_2Cl_3 = 196 = Au$$
$$Fe_3S = 197 = Au$$
$$C_2H_5I + \tfrac{1}{2}\,Br = 197 = Au$$

He uses both 196 and 197 as the atomic weight of gold to suit his purposes, and seems to be very weak in arithmetic, for the hypothetical body Fe_3S has a molecular weight of 200.

The ammonium-ferrous-sulfate crystallized with six molecules of water, which chances to have a molecular weight equal to that of gold, is used by Strindberg as basis of the following experiment, which serves to show his method of reasoning and of operating.

Ammoniacal sulfate of iron = 392 = Au is perhaps the solution of the enigma; sulfate of iron (green copperas), precipitates solutions of gold; to precipitate according to monist-chemistry is to enter as a factor into the reconstitution of the body of a compound. Soak a strip of paper in a solution of sulfate of iron, and expose to the fumes of ammonia; the paper will assume a bluish-green color like that of the protoxid of gold. Dry the strip of paper over

a lighted cigar and the paper will acquire a chestnut-brown color like that of the deutoxid of gold. Little by little metallic flakes of a golden yellow color appear, forming a non-solid (*non-fixé*) gold, when the sulfate of iron produces an auto-fecondation by self-precipitation. However, the golden flakes amalgamate with mercury, which property is not shared by iron. After showing by appropriate tests that iron is still present the hermetic chemist proceeds to explain the reaction by assuming the formation of the hypothetical $Fe_3S = 196 = Au$, or of the imaginary compound

$$Fe_2O_3 + 2H_2O = 196 = Au,$$

or of the

$$\text{ferrous-ammonium-sulfate} = 392 = Au_2;$$

and he adds, 'The chlorid of gold is reduced by the nicotine of the cigar.' Since, however, no reagent containing chlorin in any form was used in the experiment, this element must have been created at the same time with the gold, which, however, is 'incomplete' gold soluble in unmixed acids.

A preacher should never be judged by a single sermon, and to do justice to these nineteenth century alchemists, one more 'recipe for gold' may be transcribed. "Put into a crucible layers of sheet iron and of powdered vitriol; place over it another crucible pierced with a hole for respiration. Heat in an intense fire. But a flux must be added to the crucible to prevent melting, viz: One kilo litharge, one kilo clean white sand, mix and add to the crucible at a red heat. Remove with an iron spoon the yellow oil and put it aside. The two compounds have not lost weight. This oil is dry water, a fire, a salamander. * * * You obtain a metal of a golden yellow, having a density of 24, not capable of being minted. This is changed into ordinary gold." With the exception of a few unimportant sentences, this is the entire recipe, but how the final transformation is to be effected is not given.

To acquire knowledge and power for successful hermetic labors, to become eligible for initiation in the occult societies, is no easy task. The aspirant must strive valiantly against the passions that assail him, casting out of his soul pride, anger, jealousy, hatred, avarice, hypocrisy, idleness. If the candidate for honors desires to become worthy of the name hermetic philosopher he must prove himself a Magian; he must learn to exercise his will on matter in all its forms, and to acquire this power he should practice crystal-gazing and reading in magic mirrors; to learn to perceive the invisible he must withdraw from the visible, imposing on himself psychic sleep, called by some hypnosis. As adjuncts to the attainment of the ideal mental state he should use perfumes, music and light; and eventually the astral body, separated from the physical body, will supply the intellectual, moral and material illumination indispensable to the Great Work.

It is rather discouraging to learn that, even after fulfilling all these hard conditions, no one can realize the perfection desired until he has passed through several of our planetary existences. The would-be alchemist must also follow the percepts of Albertus Magnus; he should be discreet, silent, and must not reveal the result of his labors; he must reside in an isolated place and choose the time and the hours for his tasks; he must be patient, assiduous and persevering, and he must be rich enough to bear the expenses of his pursuit. Besides ordinary chemical apparatus he should provide several objects indispensable to his work, a magic wand, a sword to dissolve the astral coagulations, a magic mirror, a brazier for perfumes, a wooden altar covered with a white cloth, and an alchemist's robe of white linen to be worn with a girdle

embroidered in gold and silver. In all his chemical operations he must project psychic force into the reagents.

Bright prospects for the future of chemical science are claimed by this school of philosophers. Inorganic chemistry is destined to follow the lines in which inorganic chemistry has prospered; the formation, derivation, or rather the evolution of metalloids (so-called) and of metals will be realized through etheric cyclones, different degrees of condensation of hydrogen. Chemical bodies are of one kind only and they are all organic and living.

There is a growing belief among advanced chemists in the theory that the elementary bodies as known to us are compounds of a unique primary matter (*protyle*), and that transformation of one kind into a similar one is not beyond the bounds of possibility, but we do not think that the modern hermetists are pursuing the right path to accomplish this end; nor do we believe that the world of science is any nearer the coveted goal of alchemical avarice.

The revival of alchemical pursuits in France finds concurrent sympathy in other parts of the world. Especially does this pseudo-art flourish in India, where the Sannyassis, a caste initiated in occultism, practice the transmutation of tin, zinc, copper and mercury into silver, or at least into a metal resembling silver superficially. In the published recipes for effecting this change arsenic plays a prominent part, a substance used for the same deception by the alchemists of the Middle Ages. In China a belief in alchemy has existed from very early times; reprints of ancient treatises are still for sale, and the experimental phase is quietly studied by semi-educated persons.

In the United States two notable events have occurred within twelve months, one of which seems to threaten financial revolution. A bold claim to manufacture gold of pure antimony has been made by Edward C. Brice, of Chicago; having been refused a patent on his process by the United States Patent Office, he demanded a test to be made, and three assayers of the United States Mint conducted the trial under Brice's instructions. Needless to say, the experiment did not verify the claim; the assayers found that all commercial antimony contains a trace of gold, and that Brice did not even recover the whole of this by his process. Brice's previous record does not bear the full light of investigation, so that this attempt to revive alchemical practice is on a par with many that have preceded it.

Quite different seems to be the equally bold claim of Dr. Stephen H. Emmens, that he has discovered a body intermediate between silver and gold and capable of being changed into gold; this substance he has named *argentaurum*. Dr. Emmens, who is an Englishman by birth, is the author of many books on a great variety of topics; a treatise on logic, another on explosives, several novels and many papers on chemistry, electricity and metallurgy as well as some poems show his versatility. He is a member of several learned societies, and inventor of the high explosive 'emmensite.' Dr. Emmens has established a laboratory for the manufacture of gold from silver by a secret process in which mechanical treatment plays an important part. Since April 13, 1897, he has sold to the United States Assay Office six ingots of an alloy of silver and gold for the gross sum of $954, as proofs of his success in transmutation. This matter having been exploited in the daily press, details need not here be reproduced.

In the United States, where education is so general and a shrewd, calculating, 'Yankee' spirit looks askance at such enticements, alchemy is not likely to flourish; on the other hand, hermetism, the meta-

physical phase of the philosophy seems far more likely to be cultivated by the devotees of theosophy and esoteric studies.

In conclusion, a passage from Lord Bacon: "I was ever of opinion that the philosopher's stone and an holy war were but the rendezvous of cracked brains that wore their feather in their heads."

H. CARRINGTON BOLTON.

WASHINGTON, D. C.

---

*SCIENCE IN EDUCATION.**

DURING the year 1895–96 there were in attendance at the colleges and universities of the United States nearly fifty thousand students who were pursuing courses leading to the degree of Bachelor of Arts, and of whom nearly ten thousand received that degree. In the various technological and professional schools there were sixty-six thousand students and nearly or quite fifteen thousand graduates. That is, those students seeking the so-called liberal education were less than forty per cent. of all the candidates for college degrees.

In none of the professional schools, with but few exceptions, is the possession of a college or university degree necessary for admission. A single medical school at the present time requires its matriculates to possess the bachelor degree, and some others will in the near future. In the theological schools a preparatory college education is more usual, but the whole number of theological students in the United States is relatively small, and does not seem to be rapidly increasing.

Nearly one-half of the professional students are those studying medicine, and of these I do not think more than five per cent. are graduates of other courses. Less than that percentage will be found among the engineering students, for reasons that will appear later. The profession of law, which is yet far behind the other professions in its educational requirements, has less than ten thousand students in attendance upon college instruction in our country, not one-third of the number of the medical students, though the members of the two professions in practice are much more nearly equal in numbers. A much larger proportion of arts graduates turn to the legal profession than to any other, in part due to the fact that the educational requirements of the legal profession are, in general, on so low a plane that the earnest young man is not content to enter upon his life's work with so slight a college preparation as it demands; in part because the ordinary college course offers better preparatory training for the legal profession than it does for any other, save the theological or pedagogic.

I am not aware of any statistics of the number of arts graduates among the active members of the professions in America, as a whole, but the number is clearly very small, certainly not one in ten, and I believe that there can be no question but that the percentage is steadily becoming less from year to year.

Our first impressions are that this fact is to be deplored. I believe, however, that it is rather matter of congratulation, inasmuch as it certainly means in the end better preparation for the active duties of life by the great body of professional men.

In no branch of education has there been more active progress than in that of medical education in the United States during the past fifteen years, and in none has there been a larger proportional increase of students. Twenty years ago, with almost no educational requirements for matriculation, nearly every medical institution in this country would graduate the average student after two courses of lectures, the second a repetition of the first, and each of but four or five months' duration. I have known students of average ability to re-

* A presidential address before the thirtieth annual meeting of the Kansas Academy of Science.

ceive the diplomas of some of the most renowned medical colleges of the United States whose entire medical tutelage was comprised within a period of less than one year's extent.

At the present time many require four years of college work, or shortly will, and these college years are often eight or nine months in length and are never less than six. Furthermore, they are not mere repetitions, but are graded from entrance to graduation with constant laboratory practice and frequent examinations. When the course was of but two years' duration more students relatively sought preparation in a more liberal education in the college of arts, for the same reason that seems to actuate many law students. Many of the law schools now require but two years' attendance upon college work and practically only nominal preparation for admission, and the majority of the practicing lawyers of our country have had no college professional training at all. The better colleges are now extending their course to three years, and it is only a question of a short time when the period of college study necessary for the reception of the legal diploma will be equivalent to that of the medical profession.

The modern educational requirements of the medical profession have, I believe, raised it to a distinctly higher plane than that of the law. To use the words of Justice Brewer: "A growing multitude is crowding in who are not fit to be lawyers; who disgrace the profession after they are in it; who in the scramble after a livelihood are debasing the noblest of professions into the meanest of avocations; who, instead of being leaders and being looked up to for advice, are despised as the hangers-on of police courts and the nibblers after crumbs which a dog ought to be ashamed to touch."

But this condition will not last long. The time will soon come when everyone who appears before the bar of justice as an advocate will be a thoroughly educated man or woman. And does this mean that he will be required to have a four years' education in the college of liberal arts? Most certainly not. A four years' course in the law school will be required, whose certificate will carry with it the educational right to admission to the bar, and little or no attention will be paid to the so-called branches of liberal culture.

Conditions have changed much. The greatly increased competition and the greater struggle for existence now render it imperative that the professional man should be better grounded in the principles of his profession than he once was. The great accumulation of scientific knowledge has left the teas, the simples and the boluses for the quack in medicine. The lawyer can not be a politician, a real estate or insurance agent, and, in the intervals of his avocations, do justice to his client. The professional man can not spend much time in purely cultural and æsthetic studies, while his competitors are spending theirs in acquiring a knowledge of how to treat their patients or how to execute a legal document.

The average course in the college of liberal arts does not prepare for the studies of the medical profession, and not many physicians now urge young men to pursue the course in arts as a preliminary to professional training. A part of that time certainly is better spent in the more thorough mastery of the professional education.

The average age of graduation from the college or university at the present time is nearly twenty-three. The ambitious graduate in medicine will desire to give at least one year to hospital practice, or to travel before beginning his more active duties. He is then twenty-eight years of age, and two or three years more will certainly be needed

before he becomes an independent member of society.

And this is not the worst of it. In the profession of medicine, as in all other professions, book-lore or professional lore is only a part of the foundation for successful practice. A knowledge of mankind, of men and women, is more essential than a finished knowledge of his profession. At twenty-seven or twenty-eight a man is too old to acquire this knowledge in the best way; the plasticity of youth is waning, and new habits are hard to form. He must remain more or less controlled by his student habits, out of intimate touch with the great mass of the people and their inner life. And this lack of knowledge of human nature must surely remain as an obstacle to the most useful and successful practice.

President Eliot has said: "The average age of admission to Harvard College at this moment is fully nineteen. The student who stays here four years is twenty-three years old when he graduates. He then goes to our medical school to stay four years; so he is twenty-seven years of age before he has his medical degree, and we all know that some years intervene between that achievement and the competency to support a family. Now, that highly educated young man ought to have married at twenty-five."

The same conditions will surely confront the lawyer before long, and not only the lawyer, but the dentist, the theologian and students of other learned professions.

An answer that is brought as a solution for this unsatisfactory state of affairs is that the fault is in the preparatory schools. That poor teachers and poor teaching make the work of preparation for the college longer than need be, is very true, but I do not think that any relief obtained here will influence students toward the college of liberal arts. As teaching in the secondary schools become better and more efficient, other subjects will be crowded into the high school course, filling in all the time that is saved. This will be of added advantage to the professional student and will more and more tend to lead him away from the college of liberal arts. Furthermore, none of the colleges of the United States have shown much, if any, tendency to shorten the course leading to, or render less difficult the requirements for, the Bachelor of Arts degree.

The entrance requirements for the medical and law schools are at the present time very unsatisfactory. The medical schools have labored unceasingly to increase them for the medical degree, during the past ten years, so far as professional knowledge is concerned, but they have done very little towards increasing the requirements for admission to the schools. In very few schools are they at all equivalent to those for admission to the freshman class in the better colleges of liberal arts. A very little knowledge of some foreign language, usually Latin is required; a little mathematics and a little physics, and a passable knowledge of English; but the student needs very little of what the world calls liberal culture, and practically nothing whatever is demanded.

After considering these chaotic entrance conditions to the professional colleges of law and medicine, it is refreshing to turn to another, in which, with but little pretension, with modesty and deprecation, rather, a model has been set which all the other professions will, in the end, surely follow.

The engineering profession to-day is, upon the whole, the best educated in America. While there may be a smaller proportion of highly trained men, there is also a far smaller proportion of poorly trained ones than in either medicine or law. It may seem strange that that profession which comes less into immediate contact with the general public should be, upon the whole, more highly trained than

those which touch so closely the pecuniary and physical well-being of every one. But the reason is not hard to find. The engineer is judged more by his peers, while the lawyer's or physician's success is dependent very largely upon the public. The capacity of the engineer must invariably be made apparent to men of affairs and ability, while the lawyer or physician is judged, for the most part, by those who are incompetent to determine his real merits.

Undoubtedly, as the years go by, more rigorous requirements will be demanded from the engineer, as from the lawyer and physician, but I do not believe that they will ever be very great in extent, save as new methods of teaching are developed, and these will require ability and capacity rather than time. The engineer may enter upon active life at the age of twenty-four or -five at the outside, fully grounded in the principles of his profession. No gap is left in his education between the high school and his strictly professional course, but the one grades into the other in an harmonious way. Though he graduates with the commonplace degree of Bachelor of Science, it represents, on the average, more college work than does that of Doctor of Medicine.

If, then, the learned professions are drifting away more and more from the college of liberal arts, what is the object of a general college education? What does the average young man or young woman have in view when he enters upon a four years' course leading to the degree of Bachelor of Arts? Undoubtedly the larger number have nothing definite in view. They are actuated, for the most part, by the desire for a better education, without any clear idea of what they wish to accomplish in life. Had the student in the high school a definite conception of his future work in life he would be more apt to seek that special training which would most enhance his prospects for success. Many of the universities and colleges have endeavored to attract those students who have determined upon their life work, and who would otherwise skip the general college course, by offering some choice of studies, or by permitting the last year in the course for the arts degree to be spent in the professional school. This system of optionals has, perhaps, reached its highest development at Harvard and Leland Stanford Universities, where not only great latitude is allowed in the entrance conditions, but the whole college course is made up more or less fully of optional studies. That this system has been popular is shown by the more rapid growth of these and similar institutions as compared with the more conservative institutions, where many of the older classical requirements are yet rigidly insisted upon.

But, the system of optionals has gone quite far enough in some directions, not far enough in others. The average student, who has not yet made up his mind what he will do with himself, is bewildered and confused by the multiplicity of studies opened up before him. He is not competent to judge what is best for himself, and he needs at this time, more than at any other in his life, the advice and assistance of those who have gone before him over those labyrinthine roads; and he rarely gets it. The study of Chinese jurisprudence seems to have as much importance in the college curriculum as do other subjects, and, if the teacher is popular or 'easy,' he selects it. If he is working for his degree, as unfortunately most undergraduate students in the college are, he picks out the 'soft snaps' in college parlance and tries to double up on his studies that he may get through the sooner. Throughout all his preliminary course in the high school, as well as in his freshman and sophomore years, the study of language and mathematics has been strongly emphasized and he has had hardly

a glimpse of any other branch of knowledge. In the name of common sense, then, how can he be expected to have acquired any taste whatever for unrelated and dissimilar studies, or to have any conception of their relative importance? His advisers have been chiefly linguists and mathematicians, whose ignorance of the natural sciences is often equalled only by their prejudice against them. It is a fact that the larger proportion of those who have become students of the natural sciences have had their inclination formed despite of rather than by means of the university. The university seldom intimates to them that science studies ought to form an important part of their general training.

The result of all this desultory or biased study is that the student usually graduates without any clear idea of what he will do in life. He rarely studies with any definite aim, save that of getting an education, of the value of which he has little conception. He has been taught to believe that the best possible preparation for success in any department of life is a liberal education, and he does not trouble himself much as what his future career may be, resting self-satisfied in the delusive assumption that he will be fitted to enter upon anything.

It is true that the most earnest students that we have are those of the professional schools. A distinguished teacher of engineering has said: "It is unquestionably a fact that the engineering students of our colleges do more and harder work for a degree of equal grade than do the students of other departments." As a teacher of medical science I know that the average medical student does fifty per cent. more work than those of like capacities in the undergraduate arts courses. There can be no denial of the fact that the most earnest students are those who seek knowledge as a direct means of success in life rather than for the mere pleasure of its possession.

I believe, therefore, that the principle, now so largely adopted, which permits the student to browse about at his own will with a nibble here and a bite there, is wrong. He should be permitted and required early in his life to gaze upon the broad field of knowledge and at least to taste some of its enjoyments, in order that he may find out what his best and easiest path will be towards success. Away with the mediæval idea that a course in arts fits a man for anything. It does not and never will, unless it changes very much from what it yet is. As we have seen, the degree of Bachelor of Science in engineering, to which we may also add that in pharmacy, represents a larger degree of training and a greater knowledge than that possessed by the Bachelor of Arts. Why, then, does the latter assume such transcendent importance in education? Solely upon the claim of culture. How many are the sins that are committed in thy name! The classical student who has devoted five or six of the best years of his life to the study of the ancient languages, with little or no attention given to the modern sciences, is dwarfed and narrowed in his conceptions of life, even as the scientific student would be with no knowledge of the languages. Horace Greeley meant just such students as these when he said: "Of all horned cattle, deliver me from the college graduate." I by no means wish to deprecate the study of language and of philology. They are among the noblest that the student may undertake and well worthy of the ardent pursuit of the specialist. So, too, are the professions of law and medicine, but no one will presume to say that everybody should be a lawyer or a physician in order to be cultured.

At Yale College not less than nine or ten years of foreign language study are required for graduation, and not one week of any natural science. In the University of

Kansas, which may be taken as an average type of the Western universities, five years' study of foreign language must be had, and nothing whatever of any biological science.

Is that department of human knowledge which, more than all others, has been the foundation of the civilization of the present century; which has done more to lengthen life, to ameliorate its burdens, to improve, purify and advance the world; which has furnished one of the great underlying principles of modern education, of which even the philologist boasts—laboratory methods; which has established the great underlying principle of all progress—evolution; is this department of knowldge, I say, of so little importance that it is practically ignored in the requirements of a modern liberal education? Twenty-five years ago the classical course was the almost invariable one in our colleges; but even in those times I was required to learn the rudiments at least of physics, chemistry, botany, zoology and geology. Now modern education has liberalized the course by making the larger part of the language studies compulsory, and all, or nearly all, the natural sciences optional!

But the writing on the walls is so legible that he who runs may read. Yale College, the great exponent of the classical course, has been almost the only prominent college in the United States that has not gained materially in attendance during the past two years. Harvard, more liberal, does not insist upon so extended a study of the ancient languages, and will permit a considerable amount of science to be offered in their stead. Columbia College, which, until recently, has had requirements almost like those of Yale, has so modified its course that Greek is no longer demanded. To quote from its recent catalogue: "No one can obtain the degree of Bachelor of Arts who does not know something of at least one ancient language, and who has not therefore looked out through this window upon the world of antiquity. He must know also something of history, something of philosophy, something of political economy, a good deal of English, something of mathematics, and something of a least one natural science. He must also have a reading knowlege of French and German." It is refreshing to learn of one college that does require the student to leave that window of antiquity long enough to learn something of one natural science, of the laws that control the world and its inhabitants. We may be profoundly thankful that all the universities do not insist that we shall look out through two windows upon the high morality and civilization of the old Romans and Greeks.

In thus claiming some recognition for natural sciences in the course of liberal arts I shall doubtless be accused of narrowness. I trust, however, if I am, that it will not be imputed to ignorance of the classical course. I studied, when a youth, Latin and Greek for the prescribed time of six years each, and have since learned to speak or read three or four of the modern languages.

But I do more than claim recognition for the sciences. I claim broadly and emphatically that the natural sciences, any or all of them, are as valuable and as necessary as pure cultural studies as are the languages; that intelligent and successful study of them will do as much, if not more, in making the student a broad man, a successful man, as will the study of Latin or Greek. And they will do more in making him an honest man. Nowhere in all the broad field of knowledge will he learn better to think exactly than in the natural sciences. Nowhere will he be more impressed wih the importance of truth for truth's sake.

Among the graduates of the University of Kansas, with whom I am best ac-

quainted, there are not more than one-half who have had any training whatever in the natural sciences, with the exception of about ten weeks in physics and as many in chemistry, and perhaps a smattering of physiology. The simplest facts in natural history are as utterly unknown to them as is the prosody of the Hebrew language. A little, a very little, of biological science has been absorbed in the reading of fiction, of history and the newspapers.

The simplest functions of their own bodies remain for the most part sealed mysteries, the commonest laws of nature inscrutable. In fact, the ignorance of nature as a whole among the majority of the graduates of the so-called liberal colleges is usually abysmal in its profundity, stygian in its opacity. In the rules of philosophy they may be able to 'distinguish and divide a hair betwixt south and southwest side,' but are unable to tell the difference between granite and limestone, a polywog and a porpoise. In the laws of political economy they may talk learnedly and dogmatically, but are unable to locate the liver in their own body or to tell its functions. I verily believe that a third of the graduates in arts of our universities and a fourth of their instructors could not tell whether the pancreas is located above or below the diaphragm, or whether or not they have either pancreas or diaphragm at all. Grant Allen, in the *Cosmopolitan*, says: "Quite well-informed people will speak of a porpoise or a lobster as a fish; such grotesque blunders ought to be made impossible; they ought to be considered far more damnatory evidence of ignorance and ill-breeding than 'you was' or 'me and him went there.'" With such a standard how many college graduates are there who are educated?

President Dwight, in the same periodical, says: "In any future development of the college system the chief purpose of general culture should not give way or be subordinated to any purpose of special culture with a view of some special work in future years." It is this spirit of culture for culture's sake that has dominated Yale College so thoroughly in past years and which makes the institution to-day the best type of the non-utilitarian education in America. The same conservatism is evinced in Professor Peck's attitude toward education. The classical student with him is a 'gentleman and a scholar,' while the scientific student is a 'sublimated tinker.' No wonder that he urges the unwisdom of a higher education for the masses of the people.

There is much in favor of the primary importance of mind-building in education, and no education can be the best that makes it subordinate to the mere acquisition of knowledge. But the position is assumed, by those who favor the classical education, that utilitarian studies may not be at the same time cultural; that one may not get useful knowledge and mind-building at the same time.

To use President Andrews' words: "Our strictures upon classical studies in college would have less weight were it not that these subjects crowd from the curriculum numerous others which would at least be equally suitable for college drill and incomparably more valuable later. The common opinion seems to be that, to be useful in disciplining the mind, matter for study must be useless for the purposes of life. There could be no greater error. Studies like social, political, physical and biological science, and modern literature and history, all of which are vitally important for intelligent men and women who must live and act their part to-day, are precisely the ones best calculated to enlarge, cultivate and strengthen the intellect."

The mistake that President Dwight and those who think with him make is in assuming that all men are capable of the broadest and highest culture, or that a

liberal education should be limited to those only who have such capacities. We urge upon the future student of medicine that he should pursue a liberal classical course in preparation for his professional training. He replies that he has no aspirations and no ability to be a leader among men; he seeks only the best education he can get that will fit him for a more humble sphere. He skips the college course and devotes all his time to his professional studies. In fact, the strictly classical course, such as Yale best represents at the present day, is perfectly adapted for but one class of people, gentlemen of leisure, who are not dependent upon their daily toil for their bread. One would not ask the hod-carrier to pursue a course in the ancient languages before beginning his apprenticeship. Nor should one require the same of the ordinary professional student.

As an opposite extreme to the conservatism of Yale may be cited Leland Stanford University, in which knowledge of the ancient languages is not indispensable for graduation. In this institution twenty-two subjects may be offered for admission, only one of which (English) is required, the remainder to be chosen from the twenty-one other courses. This list includes algebra, geometry, trigonometry, physics, chemistry, physiology, botany, zoology, drawing, American, English and ancient history, Spanish, French, German, Latin and Greek. In the college course certain groups of studies must be selected under advice, but this is the only restriction upon free choice. The effect that this latitude has upon the choice of studies is interesting. Of those who last year took their major work in Latin and Greek there were 76; in history and economics, 219; in mathematics, 29; in the natural sciences, 223; in modern language, 80; in English, 140. In the ancient languages 151 students were enrolled the first semester of last year; in the modern languages, 686; in mathematics, 148; in the natural sciences, 926.

The friend of classical culture may justly say that the education that seems possible at Leland Stanford is a narrow and one-sided one. A student who knows nothing whatever of the foreign languages is as surely a dwarfed and one-sided man as is he who studies the languages only and none of the natural sciences. It is not to be supposed that the students of Leland Stanford are of a different class from the students of other universities. There their choice is almost wholly unrestricted and the natural inclination away from the ancient languages is conspicuously shown. The only bachelor degree given for work in any of the lines possible is that of Bachelor of Arts.

When the old classical idea was yet so firmly inwrought into higher education that all else was leather and prunella, degrees of all sorts sprung up as mushrooms—Bachelor of Science, of Philosophy, of Pedagogy, of Music, of Engineering, of Pharmacy, of Agriculture, of Mechanics, and of goodness knows what. They were frank statements that such degrees did not mean liberal culture and were given rather as placebos. These degrees have, fortunately, largely been abandoned, the older degree of Bachelor of Arts supplanting them; an acknowledgment that liberal culture may be obtained in other ways than the old classical one.

I am aware that many will lift up their hands in classical horror at the bare suggestion that such a thing is possible as a Bachelor of Arts course in science, thoroughly convinced that the wolf has at last stolen bodily the raiment of the sheep.

The effect of the present requirements for the admission to the colleges and university of Kansas has been in a high degree disastrous to science instruction in the secondary schools. Chemical laboratories

that once delighted and instructed the high school pupils, the microscope and its world of revelations, the herbarium, the museum and the dissecting knife, have been abandoned and in their place Latin, German and French have been substituted. Of all the subjects required for admission to the State University, students come best prepared in Latin, because the requirements in this subject have been made most severe and important. Instruction in the natural sciences in the secondary schools of our State is superficial and imperfect in the highest and most astounding degree. Of all those who are candidates for the State teacher's certificate to teach the sciences it is the exception that one has as much knowledge of any branch as might be acquired by the diligent student in ten weeks of work; rare that an examination paper is the equal of those offered by the second-rate students in our University.

Put, however, the same emphasis upon botany, zoology, chemistry and geology that is given to Latin and the preparation would very soon be fully as good, fully as thorough. Let the high school scholar learn that the study of the natural sciences is deemed as valuable in his preparatory training as is language or mathematics and there will be no lack of good teachers.

Were I, then, to say what the universities and colleges ought to do it would be this: Make all the ancient language requirements for admission optional, and demand as much preparation in the physical and biological sciences as in the foreign languages. The preparation in English should be made far more rigorous and thorough. In the college course, if anything besides English is required, and I think there should be, I would have the natural science as necessary a part of the education as language and mathematics. I would not have it possible for a student to graduate from the college without having studied, and thoroughly studied, mathematics as far as trigonometry, at least one foreign language, and at least one physical and one biological science. And I do not mean a few weeks of study in any of these branches, but exhaustive, careful, critical study.

The methods of study in all these branches are diverse and are absolutely essential for symmetrical mind-building.

Furthermore, an indefinite, haphazard selection of studies in the college course should be impossible. The course should be, so far as possible, adapted to the capacities, tastes and abilities of the individual, and this does not mean an indiscriminate selection on the part of the student. A person with feebly developed chest muscles might naturally prefer those physical exercises in which such muscles would take little part, but he nevertheless needs such exercise most.

It is through the great universities, and especially the State universities, that the solution of the problems of professional education must come, and in fact has come for some of the professions. With such cultural training as is best adapted to the lawyers's needs, the college course should include all the strictly non-professional branches, leaving the student, after he has completed his course as Bachelor of Arts in law, to take up the work of the professional school and complete it in two years with the degree of Doctor of Laws. In the medical course there are even greater opportunities than in law. The medical colleges should resign to the undergraduate arts course all the non-professional branches. And the work rightfully belongs there. The best chemical laboratories in the United States are not in the medical colleges, but in the universities. Nowhere are physiology, histology and anatomy better taught than outside of medical colleges. As in engineering, there should be an harmonious course leading through the high school to

the Bachelor of Arts in medicine, preparatory to two years of strictly professional work with the degree of Doctor of Medicine.

When such training as this is demanded of all aspirants to professional practice we shall have uniformly well educated men in the professions, and not until then.

University of Kansas.

CURRENT NOTES ON PHYSIOGRAPHY.

THE REGION ABOUT LAKES TANGANYIKA AND NYASSA.

The origin by down-faulting of the linear depression holding Lake Tanganyika has been advocated by Suess in 'Das Antlitz der Erde,' and popularized by Gregory in his book on the 'Great Rift Valley.' An article by J. E. S. Moore on the Physiographical Features of the Nyasa and Tanganyika Districts (London Geogr. Journ., X., 1897, 289–300) gives additional notes of value. The south end of Tanganyika is enclosed on the west by a 2,000-foot sandstone escarpment, whence the plateau country slopes gradually westward to the shallow basin of Lake Bangweolo, whose waters are only ten or twelve feet deep; the plateau being broken by mountains of granite and gneiss which rise like islands above a sea. East of southern Tanganyika the country rises gradually; hence this part of the lake basin seems to lie in the depression between two tilted fault blocks, rather than in a *graben*. Passing southeast, the north end of Nyasa is found to lie between sandstone escarpments on either side, the enclosing uplands consisting of an uneven crystalline foundation whose depressions are occupied by sandstones and conglomerates like those around Tanganyika; this part of Nyassa is, therefore, regarded as a down-faulted rift. But going on to the south end of the lake and to its extension in Lake Shirwa, Moore finds nothing suggestive of great faults or rift valleys. Lofty granitic masses, with axes about north and south, enclose wide areas of waste slopes and alluvial flats, whose central depressions are occupied by malarial swamps and shallow lakes. The outflow by Shire river descends to lower plains through the Murchison cataracts.

It does not seem to be fully proved that the depressions between the granitic ranges were not produced by dislocations, although it is true that, in the absence of the heavy sandstones, faulting is not easily demonstrated. It may also be questioned whether the existence of the depressions 'now more or less completely filled up with decomposed granite and gneiss annually swept down into them from the hills by the prolonged tropical rain' prove that they 'have undoubtedly at one time been covered by water.' It may be added that the rains are not, properly speaking, 'tropical;' Dove having advisedly limited that term to the rains produced where the trade winds ascend mountainous slopes; the rains here are subequatorial, dependent not on the trade winds, but on the annual migration of the meteorological equator from the geographical equator.

BRÜCKNER'S ERDRINDE UND IHRE FORMEN.

The fifth edition of the standard Allgemeine Erdkunde, originally by Hann, Hochstetter and Pokorny, has for its second part a volume of 368 large pages on 'Die feste Erdrinde und ihre Formen,' by Professor E. Brückner, of Berne. It is a thorough and comprehensive work, but in its inclusion of Geology it illustrates how far Erdkunde departs from its supposed English equivalent, Geography. A quarter of the book is given to geology, including petrography, structure and stratigraphy half of the pages treat of the processes that determine surface form, and the remainder are devoted to the forms themselves. Internal processes produce volcanoes, earthquakes, shore changes and deformations.

External processes are grouped under ground water, weathering, sliding, rivers, glaciers, winds, waves and sedimentation. Forms are classified under those of the sea and of the lands; the latter being plains, escarpments, mountains, valleys, dissected regions (thallandschaften), basins, caverns, and the large forms of the land surface (mountains, plateaus, depressions). The terse style of the book shows that its author expects those who use it to be competent teachers and faithful students. Its readers may be confident of trustworthy statements and explanations; but in the third part, with which these notes are particularly concerned, there is less consideration of the genetic correlation of parts than would be welcomed by many.

THE AGE OF VALLEYS.

THE age of a valley is a measure of its stage of development. It may be steep sided and young; it may half open or mature; it may be wide open or old. At any stage in its development it may be submerged and buried, and thus preserved until some future time when it is again revealed by weathering, like any other fossil. In this sense the valley, whether young or old, may be dated as geologically ancient or modern. Thus there were mature valleys in ancient times among the St. Francis mountains of crystalline rocks in southeastern Missouri. They are still hardly more than mature, for through nearly all Paleozoic, Mesozoic and Cenozoic time they have been buried; they have only in comparatively recent time come to light again, as their relatively weak sedimentary cover has weathered off. But in another sense these mature valleys are modern, for they have been re-excavated in late post-Tertiary time. When the ancient and modern valleys coincide there may be confusion if they are briefly described as 'of very ancient origin,' and this confusion appears to enter in the paragraph given to the deep canyons of Labrador, in Adams' review of Low's report in a recent number of SCIENCE (Nov. 13, 741). The implication here, as in the original report, is that the valleys have been valleys ever since the time of their ancient origin. The probability is very great that during most of the intervening time they have been buried, and that however ancient was their initial excavation their present re-excavation is relatively modern.

HARVARD UNIVERSITY.

CURRENT NOTES ON ANTHROPOLOGY.

THE QUESTION OF VARIATION.

Two recent essays on variation as applied to man may be mentioned together, although they treat the subject from different points of view. The one is by Professor Virchow, in the Proceedings of the Berlin Academy of Sciences for 1896. He describes the difference between diathesis, *Anlage* and variation, the former being the permanent, the latter the changing factor of the organism. He points out the important fact that progressive variation may arise from pathological inceptions. While his article has the greater bearing on questions of medical science, it has valuable application in anthropology.

The second article is by Professor Mahoudeau in the *Revue* of the Paris School of Anthropology for July of this year. It is taken up principally with pointing out the exact meaning of variation or transformation in organic life as laid down by Lamarck. The quotations show that he distinctly taught the descent of man from lower forms of life. In these respects he is claimed to have anticipated the most modern doctrines in his celebrated work, first published three quarters of a century ago.

THE CITY OF OMITLAN.

A year or so ago the newspapers mentioned the discovery of a ruined city in western Mexico by Mr. William Nivens. Since then collections have been brought to New York City, and ample means thus furnished to judge of its characteristics. In the *Bulletin* of the American Geographical Society for July of this year, Mr. Nivens has a short article on the subject. The ruins are very extensive and indicate a skill in stone work above that of many tribes, but decidedly inferior to that of the best Aztec civilzation. His article speaks of a tablet with hieroglyphic characters, but examples of such are extremely rare, and perhaps of doubtful origin. The stones are, as a rule, not dressed with skill and the structures were not lofty. From all this we may conclude that we have in these extensive remains the relics of an inferior, subordinate culture-center of Aztec civilization; but this, of course, does not in any way diminish the interest which attaches to Mr. Nivens' explorations.

THE CAVE OF LOLTUN.

Loltun is the name of a remarkable cavern in Yucatan. The Peabody Museum of Archæology has just published a report of its exploration by Mr. Edward H. Thompson, in 1890–91. It is unfortunate for Mr. Thompson that the Museum waited six years to print his interesting account, as in the meanwhile another expedition, led by Mr. H. C. Mercer, of the University of Pennsylvania, carefully explored and promptly printed a full description of it in 1896. Boards of publication should be aware that the world gives credit not to him who first investigates, but to him whose investigations are first placed for use before students.

The report is well printed with attractive illustrations. The excavations were carefully made and confirm the opinion advanced by the later expedition that those who entered or dwelt in the cave belonged to the same race and people, and possessed the same culture, as those who built the great stone structures on the surface near them. Neither here nor elsewhere in the Yucatan caves did Mr. Thompson discover any signs of a distinctively 'cave people,' or of an earlier, ruder civilzation.

University of Pennsylvania.

NOTES ON INORGANIC CHEMISTRY.

To Berthelot's researches we owe very much of our knowledge of the chemistry and technology of the ancients. In the last *Comptes Rendus* he recounts his examination of glass mirrors found near Reims, dating from the third and fourth centuries. The glass was coated with a metal and also a whitish layer. The metal proved to be lead, with no trace of gold, silver, copper, tin, antimony or mercury, nor was there any organic substance present, showing that no extraneous material was used to cement the lead to the glass. The mirrors appeared to have been cut from hollow blown glass globes, and it is probable that, before being cut, the molten lead had been poured into the interior, adhering to the previously warmed glass. The whitish layer consisted of lead carbonate and lead oxid formed by the oxidation of the lead coating, and calcium carbonate, which had been deposited from the water of the vicinity. A similar method of coating glass with lead was known in the thirteenth century. In the same find were fragments of glass showing the lustre of gold and of silver; these metals were not present, but the color was due partly to the lamellation of the glass and partly to a very thin layer of calcium carbonate which had been deposited on them.

In the *Chemiker Zeitung* Léon Franck describes experiments with the every-day use of spoons, forks and vessels of aluminum.

The metal was 99 per cent. pure, containing varying quantities of iron and silicon. A boiler of 732 sq. cm. surface lost in three years' daily use 0.1046 gram, a daily loss of 0.09 milligrams. Another boiler of the same size in which milk was boiled twice a day for fifteen minutes lost in three years 0.5138 gram. An impervious coating seemed to be formed on the metal which protected it from further action. This was shown by experiments with sheet aluminum, which was boiled daily three hours with water, and which suffered greater loss near the beginning of the experiment than at its close. Forks and spoons lost very little by constant use at meals, and the same was true when used for salads, and also when used in cooking. After three years' constant use coffee spoons showed a loss of from 0.032 to 0.036 grams and tea spoons from 0.0206 to 0.0244 grams. These experiments would tend to show that for ordinary table purposes aluminum is a safe metal to use, and that it is also safe for vessels for boiling water. A similar series of experiments where salted foods and vegetables were cooked in aluminum vessels would be interesting and valuable.

IN the *Zeitung für Beleuchtungswesen* Paul Wolff discusses the question of acetylene generators. Most generators depend upon the removal of the water from the calcium carbid by the pressure of the gas to stop the action of the generator. The author shows that this is not sufficient. There are three causes for the action of the water on the carbid not ceasing. 1. The gas in the carbid chamber is saturated with water vapor, and the water is continually evaporating into this chamber. 2. A part of the water is taken up by the warmed lime and given off on cooling. 3. The carbid above the water is continually absorbing water. These difficulties may be obviated to some extent by providing that the water chamber be separated as completely as possible from the carbid chamber, as in a Kipp apparatus, but even then the action will go on until all the water present, as vapor in chamber and absorbed by the lime, has been exhausted. It is thus imperative to provide a gas reservoir large enough to contain all the gas which may, under these circumstances, be evolved after the gas has been turned off. The author in the article discusses the necessary size of this reservoir for different generators.

J. L. H.

SCIENTIFIC NOTES AND NEWS.

THE will of the late Dr. George H. Horn gives his valuable entomological collections, together with his entomological books and instruments and an endowment of $200 per annum, to the American Entomological Society. From the residuary estate, after the death of his sister, the Entomological Society is to receive $5,000, the Philadelphia Academy of Natural Sciences $1,000 and the American Philosophical Society $500.

LATE advices from the Pribilof Islands state that many yearling fur seals branded as pups in 1896 made their appearance on the hauling grounds in September and October; also that over 5,000 pups and 180 adult females were branded this year. Apart from the practical bearing of this work it will furnish definite evidence of the movements of the seals and show to what extent the females resort to the rookeries on which they were born or on which they first appeared as two-year-olds.

MR. CHARLES WALLACE HUNT, New York, has been elected President of the American Society of Mechanical Engineers.

PROFESSOR JACOB REIGHARD, of the zoological department of the University of Michigan, has been appointed by Governor Pingree a State delegate to the National Fishery Congress to be held at Tampa, Fla., January 19, 1898.

FURTHER jubilee medals have been conferred upon Dr. Günther, President of the Linnean Society; on Professor Dewar, President of the Chemical Society, and on Professor R. Meldola, late President of the Entomological Society.

PROFESSORS O. HERTWIG, F. E. Schultz, Berlin, and A. Fick, Wurzburg, have been elected corresponding members of the Munich Academy of Sciences.

WE learn from *Nature* that Professor A. Bauer has been obliged, on account of ill-health, to decline the office of President of the third International Congress for Applied Chemistry, which is to be held next year at Vienna, and Dr. H. R. von Perger has been elected in his stead. There will be twelve sections in connection with the Congress. Among the subjects to be discussed is the introduction of uniform methods of analysis of chemical products.

ALONZO S. KIMBALL, since 1872 professor of physics at Worcester Polytechnic Institute, died at Worcester on December 2d, aged fifty-four years.

THE death is announced of Dr. Louis Calori, elected as long ago as 1830 professor of anatomy in the University of Bologna. He made important contributions to human and comparative anatomy, including extensive researches on the Reptilia.

DR. M. FORSTER HEDDLE, best known of British mineralogists, died at St. Andrews on November 19th, aged sixty-nine years.

WE also regret to record the deaths of Dr. Wilhelm Blomstrand, professor of chemistry in the University at Lund; Dr. Nikolaus Kleinenberg, professor of comparative anatomy at the University of Palermo; Dr. Wilhelm Moericke, docent in geology in the University of Freiburg.

MR. J. G. SUDBOROUGH, University College, Nottingham, writes to *Nature* calling a meeting of the British students of the late Victor Meyer, in order to raise a memorial to him, to be erected in the Heidelberg lecture theater. His former students in America would doubtless be glad to join in such a memorial.

THE American Institute of Homeopathy has been successful in collecting funds for a monument to Hahnemann. It is said that as much as $75,000 has been collected and that the bronze statue by Mr. C. H. Niehaus will be dedicated during the spring at Washington.

THE New York Board of Estimate and Apportionment adopted unanimously the plan for the New York Public Library prepared by Carrère & Hastings.

BY the will of the late Warren G. Roby, of Wayland, Mass., the sum of $28,000 and half an acre of land has been left to the town of Wayland for a public library.

THE National Museum of Santiago, Chili, has purchased, at a cost of about $7,000, the valuable collection of Peruvian antiquities made by Mr. Nicolaus Saenz.

THE centenary of the Natural History Society of Hannover will be celebrated on December 15th and the two following days.

Nature states that M. Moureaux has just completed the installation of the new magnetic department of the Parc St. Maur Observatory, and it was set in operation on December 1st. The work at the old magnetic rooms will be continued until January 1st, in order to supply M. Moureaux with a sufficient number of observations for a reduction of the valuable records obtained continuously during a number of years.

A PASTEUR INSTITUTE has been established at the University of Montpellier.

THE Romanes Lecture at Oxford University next year will be given by Sir Archibald Geikie.

DR. G. F. JACKSON opened the winter course of lectures at the Imperial Institute on November 19th, the Prince of Wales presiding, with an account of the results of the Jackson-Harmsworth Expedition, on November 22d. Mr. E. S. Bruce lectured on 'Electric-Balloon Signaling applied to Scientific Exploration in Arctic and Antarctic Expeditions.' Other lectures announced for the course are illustrated lectures on 'The Wild Kafirs of the Hindu Kush,' by Sir George Scott Robertson, and on 'The Mineral Resources of British Columbia and the Yukon,' by Mr. A. J. M'Millan, of Rossland, British Columbia, formerly British agent for the government of Manitoba, who has been specially supplied with specimens, etc., to illustrate the lecture by the government of British Columbia. Professor W. C. Roberts-Austen, C.B., F.R.S., will lecture on 'Canada's Metals,' and Mr. Boverton Redwood on 'The Petroleum Sources of the British Empire.'

ARRANGEMENTS have been made for lectures by Professor Shaler and Professor James, of Harvard University, before the Teachers' College, New York.

DR. FRANZ BOAS, of Columbia University, lectured on December 3rd at the Peabody Museum, under the auspices of the Harvard Folk-Lore Club, his subject being 'The Growth of Indian Mythologies in British America.'

SURGEON-GENERAL GEORGE M. STERNBERG addressed a recent meeting of the Pittsburg Academy of Medicine on the 'Relations of man and microbe.'

DR. SVEN HEDIN, to whose travels in Central Asia we have several times referred, gave an account of these before the Royal Geographical Society, London, on November 22d.

A LETTER from Mr. Charles M. Harris, who is now at the head of the Rothschilds expedition to the Galapagos Archipelago, has been received by his brother, Dr. W. H. Harris, of Augusta, Me. Mr. Harris sailed from New York for Panama on March 20th, where he expected to charter a schooner, but three of the party there died from yellow fever. Mr. Harris then proceeded to San Francisco, where he reorganized the party and reached the islands after a passage of forty days. He states that he has been successful in making extensive collections of the fauna and flora of the islands, and expects to return to San Francisco in the spring.

THE Washington correspondent of the New York *Tribune* states that Dr. Henry S. Pritchett assumed charge of the United States Coast and Geodetic Survey on December 1st. The dispatch continues: "It will be highly gratifying to scientific circles and the friends of this Bureau to learn that the President and Secretary Gage are determined that the Bureau shall be conducted on scientific and business principles and that their plans will be carried out. Dr. Pritchett was selected entirely on the recommendations of scientific men, regardless of political views. * * * * He is a worthy successor of Dr. T. C. Mendenhall, whose admirable administration of the Bureau from 1889 to 1894 is so well remembered."

IN addition to volumes of the Contemporary Science Series (Mr. Walter Scott, London; imported by Messrs. Charles Scribner's Sons, New York) requiring special notice we have received two volumes—one a translation and one a new edition, to which attention may be called. Professor Ribot's '*Psychologie des sentiments*,' of which we gave a detailed review at the time of its publication, has been translated into English, thus much enlarging the audience of the acknowledged leader of French psychology. Dr. Moll's '*Hypnotism*' has been issued in a fourth edition, being apparently more in demand than any other volume of the series. We have not the third edition at hand for comparison, but the book has been much altered and enlarged since the publication of the first edition in 1889. The popular interest in hypnotism is in part morbid, and the numerous and widely circulated books, journals and articles on the subject do not usually add much to its scientific study, while they in some cases promote credulity and amateur experimenting. Dr. Moll's book, however, is sane and scientific, and it is to be hoped that some who come for a 'sensation' may go away with an increased knowledge of mental phenomena.

UNDER the title 'An Unusual Phyto-bezoar,' Professor Trelease has published, in the Transactions of the Academy of Science of St. Louis, an account of certain balls, composed of the felted barbed trichomes of *Opuntia*, obtained from the stomach of a Mexican bull, and comparable with similar formations described in 1896 by Dr. Coville as occurring in the stomach of a horse, and composed of the calyx hairs of a species of *Trifolium*.

THE fourth and revised edition of Professor Thurston's Engine and Boiler Trials has just been issued. In the front of the book the publishers print a descriptive list of nineteen of Dr. Thurston's works.

THE explosives department of the British Home Office has, as we learn from *Machinery*, recently had under consideration the question of the restrictions to be applied to the manufacture and keeping of acetylene gas, and has conducted various experiments with the object of gaining information on this matter. The results show conclusively that acetylene gas *per se*,

when under a pressure of something less than two atmospheres, is violently explosive; whereas, at a pressure of less than one and a half atmospheres, it appears to be reasonably free from liability to explosion, provided it is not admixed with oxygen or atmospheric air. For commercial and practical purposes it is considered sufficient to allow a pressure of twenty inches of water above that of the atmosphere (*i.e.*, roughly about one and one-twentieth atmospheres), and it is accordingly proposed to draw the safety line at this point, and to declare acetylene, when subject to a higher pressure, to be an 'explosive' within the meaning of the Explosive Act of 1875. In France and Germany the authoritities have fixed the limit of danger at one and a-half and one and one-tenth atmospheres respectively, and have imposed prohibitions or restrictions on the keeping or the manufacture of the gas when it is at a higher pressure.

Two notable articles in the *Revue de Mécanique* for October are those of Dwelshauvers-Dery on the effect of compression of steam in the 'dead spaces' of steam engines, and Sinigaglia on the employment of superheating as a source of gain in thermodynamic and actual efficiency. The former finds by trial with the 'experimental steam engines' of the University of Liège that increasing compression results in increasing waste and decreasing efficiency, the loss of power in the engine more than counterbalancing the 'initial' condensation in the steam cylinders. The latter describes in the third of a series of papers the various types of superheating apparatus employed, and gives results of their use, the gain being sometimes 20 % and more.

At the Sydney meeting of the Australasian Association for the Advancement of Science, to be held in the second week in January, Sir James Hector, F.R.S., will give a popular lecture on 'Antarctica and the Islands of the far South,' and Professor R. Threlfall and Mr. J. Pocock will give a lecture to workingmen on 'Electric Signaling without Wires.' The Sydney *Morning Herald* states that the Australasian Association originated in a letter from Professor Liversidge published in that journal in 1884. The first meeting of the Association was held in Sydney from August 27th to September 5th of the Centennial year, 1888, under the presidency of Mr. H. C. Russell, F.R.S., when 850 members were enrolled. Meetings have also been held at Melbourne, with 1,162 members, in 1890, when the late Baron von Mueller, F.R.S., was President; at Christchurch, New Zealand, with 550 members, in 1891, President Sir James Hector. F.R.S.; at Hobart, with 600 members, in 1892, President Sir Robert G. C. Hamilton; at Adelaide, with 488 members, in 1893, President Professor Ralph Tate, F.G.S.; and at Brisbane, with 524 members, in 1895, when the Hon. A. C. Gregory was President. The governments of Victoria, Tasmania, New Zealand, South Australia and Queensland have each in turn given assistance to the extent of about £1,200, either wholly or in part, as a money grant towards the expenses of the session and publication of the annual volume.

UNIVERSITY AND EDUCATIONAL NEWS.

Mr. Dean Sage and Mr. William D. Sage have given to Cornell University the house of the late Henry W. Sage for a University Infirmary. They also endow the institution with $100,000 and will equip the building for a hospital, the total value of the gift being $200,000.

The will of the late Sir Thomas Elder, of Adelaide, South Australia, leaves large sums to charitable and public institutions of Adelaide, including the following: To the Zoological Society, £2,000; to the Geographical Society, £2,-000; to Way College, £2,000; to Prince Alfred College, £4,000; to the Picture Gallery, £25,-000; for a chair of music at the University, £20,000; to the Medical School of the University, £20,000, and to the University £25,000.

Mr. Andrew Carnegie has given $10,000 to the endowment of the Mechanics' Institute in Richmond, Va.

The late Sir William Mackinnon has left a legacy of £2,000 to the University of Glasgow for a scholarship, in the following subjects: (1) Geology; (2) Natural History, together with Comparative Anatomy; (3) Modern Foreign Languages; the examination in each subject to be taken in each succeeding year in rotation.

KING'S COLLEGE, London, has received an anonymous gift of £25,000 towards the liquidation of its debt.

MR. JOHN P. ASHLEY, PH.D., has been elected President of Albion College, at Albion, Mich., succeeding Dr. Lewis R. Fiske, who has resigned, owing to advanced age, after twenty years of service.

DR. E. G. LANCASTER has been appointed professor of psychology and pedagogy at Colorado College.

A CHAIR of 'tropical diseases,' with Dr. J. E. Stubbert as the first incumbent, has been established in the New York University Medical College.

A COMMITTEE has been formed in London to present a plan for a London University, to be called University of Westminster, in case the bill before Parliament meets with continued opposition. The present degree-conferring University of London would according to the plan remain unchanged, while the different institutions of London would form themselves into a faculty of law, a faculty of medicine, etc., each institution to be financially independent and only to agree on the nature and duration of the studies required for degrees and distinctions.

DISCUSSION AND CORRESPONDENCE.

IN REGARD TO THE MARINE BIOLOGICAL LABORATORY AT WOODS HOLL, MASS.

TO THE EDITOR OF SCIENCE.—A full and adequate rejoinder to the statement which appeared in SCIENCE October 8, 1897, has been prepared and is now ready. In our opinion, however, controversial matters relating to the management of a scientific institution, especially when consisting of details, statistics or mooted points, are out of place in public prints. The subject is not of general interest, and discussion of this kind tends to injure any institution in the public estimation.

The undersigned, therefore, prefer to reply only to those concerned in the matter. To this end we shall issue to all members of the corporation and others concerned a detailed reply to the charges brought by the former Trustees. Others who may feel interested can obtain copies by applying to the Secretary of the Trustees of the Marine Biological Laboratory, Woods Holl, Mass., or to either of the undersigned.

SAMUEL F. CLARKE,
EDW. G. GARDINER,
J. PLAYFAIR MCMURRICH.

SCIENTIFIC LITERATURE.

Anthropologische Studien ueber die Ureinwohner Brasiliens. Von DR. PAUL EHRENREICH. Braunschweig, Vieweg und Sohn. 1897. 4to. Pp. 168. 30 Plates.

This work ranks among the most valuable which have appeared for years in American Anthropology. It is, to be sure, somewhat limited in its area of observation, being principally confined to the states of Matto Grosso, Goyaz and Amazonas in Brazil; but this is more than compensated by the abundance and accuracy of the material, and the skill with which the author has brought it into bearing on the leading general questions relating to the American race.

These are treated in the general portion of the volume, occupying forty-five pages. It embraces two chapters, one on the aims and methods of physical anthropology and its bearings on ethnology; the other specifically on the anthropologic position of the American race. Much of the former is concerned with defining such terms as race, type, people, stem, family, etc.; with the conclusion that race means blood relationship, and that the racial characteristics and variations are the only real objects of study in physical anthropology. The author is here on thin ice, and his definitions, carefully trimmed as they are, can often be punctured. Blood relationship, *Blutverwandtschaft,* really means nothing, for, in one sense, the whole human species is related by blood; and as much might be said of other terms assumed to have a generally recognized sense. This merely shows how needful it is to settle on an international terminology in anthropology.

The chapter on the Amercan race is more satisfactory. He regards it as strictly one, in the Blumenbachian sense. As for the question, Whence it came? He regards it superfluous to inquire, as it has certainly been on the continent from remotest human antiquity, probably

under widely different geological relations, and before language had developed. He considers the following three propositions 'established beyond question:' 1. Man is as old in America as in Europe. 2. The oldest American skulls present the same type as those of the modern Indians. 3. Between the languages of America and Asia there is a gulf which cannot be bridged. (P. 42.)

The special portion of the book is divided into two parts, the one supplying the measurements on the living subjects, the other those on skulls and skeletons. Numerous illustrations from photographs, detailed tables and outlines of skull-forms greatly aid the student in obtaining clear ideas of the physical characters of the tribes mentioned. They include the Caribs, Bakairi, Tupis, Botocudos, Chaco tribes, and those of the valley of the Purus River.

The general conclusion which he draws from these extensive comparisons will be surprising to many, especially those who have said so much about the 'Mongoloid' traits of the American Indians. "So far as their physical traits are concerned, these Indians of ours approach much more closely the types of the Caucasian than of the Mongolian race. The arms and generally the upper extremities, the elevation of the symphysis and the navel, are thoroughly European." (P. 130.)

The osteological material was mainly from the Bororo, Karaya and Kayapo tribes. It is figured fully and the measurements presented in detail. Some of the skulls were of low capacity and their nannocephalic character suggests the already known relations of the people of the Purus, among whom they prominently occur, to the Arawacks of the northern shores of the continent, and to the island-dwellers of the West Indian archipelago.

The general impression left after an examinations of the craniological measurements, however, is one of wide diversity, a diversity not satisfactorily explained by the author's various suggestions of amalgamation and environment, but from its sporadic abundance, going back to sources of variation in skull-proportions which diminish their value as race criteria.

The work is furnished with a table of contents, an index of authors quoted, and one of subjects; a completeness of reference which it is a pleasure to note.

D. G. BRINTON.

The present volume is of great importance, not only on account of the detailed information given in the special part of the work, but also on account of a critical examination of the methods of somatology. The following lines are intended as a review of this general part of the work.

Dr. Ehrenreich is one of the few anthropologists who have an equal command of somatological, ethnological and linguistic methods. His criticism of modern somatology is directed mainly against the excessive weight given to measurements as compared to morphological description and to the loose use of the terms race and type.

He would reserve the term 'race' for the principal divisions of mankind, while he would call the varieties of these main divisions 'types.' He objects strongly to the application of the term 'race' to closely affiliated varieties which differ in regard to a few measurements, while their fundamental morphological features are much alike. He justly attributes much of the confusion prevailing in anthropological literature to a lack of clear distinction between the main groups and their subdivisions, and particularly to the tendency which has developed of recent years to consider a few anthropometrical criteria as a sufficient basis for the establishment of a new race.

In determining the 'races,' or the main divisions of mankind, Ehrenreich demands the consideration of three principal phenomena. He claims that each race is characterized by similarity of anatomical traits, geographical continuity of habitat, and similarity of the structure of the languages spoken by the people constituting the race. The first two points are well taken. They refer, of course, to conditions prevailing before the modern migrations of races. I doubt, however, if it is admissible to introduce the last point of view in the definition of the principal divisions of mankind. Ehrenreich is led to include languages in the characterization of races by three considerations. He says: (1) Every race has developed a greater or lesser number of characteristic linguistic stocks. (2) These stocks are not found outside

the limits of each race, excepting a few instances which are explained by certain peculiar conditions. (3) There are fundamental differences between the structures of the languages spoken by the different races, and no connecting links between them exist. Based on these arguments he distinguishes six races, leaving the position of the Papuas and of the black peoples of Asia doubtful. I will not lay great stress upon the fact that these principles of classification lose their applicability among the last-named people, as in their case peculiar conditions prevail. But there are other cases which show that these principles do not help us to establish a definite number of races. The linguistic considerations would make it impossible to include the pre-Aryan peoples of Europe and western Asia, in what Ehrenreich terms the Caucasian or Mediterranean race, although the anatomical characteristics of these peoples are identical with those of the Mediterranean race. On the other hand, the American race shows considerable anatomical uniformity as compared to other races, and, nevertheless, there is no unity of structure of language in Ehrenreich's sense of the word. It is no less possible to imagine a connecting link between the principles of structure of the Algonquin and Eskimo than between the Eskimo and Ural-Altaic languages. If we are willing to consider American languages as a unit, and include only these principles in the general characterization of American languages that hold good in all of them, there is nothing to prevent us from including Ural-Altaic languages in the same group. Ehrenreich agrees in these opinions with the views expressed by Brinton in his discussion of the characteristics of American Languages. (Essays of an Americanist, p. 350 ff.)

Dr. Ehrenreich's second criticism of modern anthropology is directed against the excessive weight given to measurements as compared to morphological descriptions. He expresses the opinion that the classification according to cephalic indices which has held sway since the days of Retzius has greatly hampered the development of somatology and has made efforts at classification futile, since these were based on measurements, particularly on indices, alone, while they must be based on morphological descriptions. These latter, he holds, cannot be replaced by numerical values. While heartily agreeing with this view, particularly with the objection to the exaggerated value given to the length-breadth index of the head, I do not think that Dr. Ehrenreich's condemnation of anthropometry is quite justified. He defines the object of somatology as the somatic investigation, description, and if possible explanation of racial characteristics. With this, I believe, all anthropologists will agree. The only question is what methods are best adapted to these ends. A broad view of the history of anthropology shows that measurements were originally introduced in order to give precision to certain descriptive features which could not be expressed satisfactorily in words. This appears to have been the leading view of Daubenton and Camper, who were the first to introduce measurements in discussions referring to comparative anatomy. The nearer alike the types which we compare, the more difficult it is to describe in words their nice distinctions. Anthropology was the first branch of descriptive biology to deal with closely allied varieties, and for this reason the need of substituting exact numerical values for vague descriptions was soonest felt. Since zoology, more particularly the study of mammals and of birds, has begun to take into consideration the geographical races of the same species we observe the same tendency of adding measurements to verbal descriptions.

In so far as Dr. Ehrenreich's criticism is directed against the substitution of measurements for descriptions that they should supplement, it is most timely and ought to be taken to heart by investigators. The terms dolichocephalic and brachycephalic as indicating two groups of head forms determined by measurements have by some investigators been raised almost to the rank of specific characters, although, as Ehrenreich justly emphasizes, and in this he has the support of Sergi, Harrison Allen and others, the sameness of the index does not by any means signify sameness of morphological type. He disclaims the significance of these characters when not supported by general morphological agreement. In all this the author is certainly right. But he overlooks entirely the principal and fundamental value of numerical measures

as illustrating the range of variability of types which cannot be given by any verbal descriptions. The type inhabiting a certain region cannot be defined satisfactorily by a substitution of descriptive features selected by even the closest observation. It is not possible, as Ehrenreich says, to represent a type by a typical individual. The description must include all the individuals in order to illustrate the composition of the group that is being studied. In order to give an adequate description it is necessary to illustrate the frequency of different types composing the group. While the types found in two adjoining areas may be almost identical their distribution may differ. The attempts to treat the same subject by means of composite photographs or composite drawings, which form a purely theoretical point seem very promising, offer serious practical difficulties which make it difficult to use these methods. The variability of a type can, therefore, be expressed only by means of carefully selected measurements. Dr. Ehrenreich states with great clearness that none of the proposed series of measurements are satisfactory, but we must add that a way exists of discovering such measurements. This way is shown in Professor Karl Pearson's admirable investigation on correlations which was suggested by Galton's important work on heredity. By its means laws of correlation may be discovered which express morphological laws. It seems to me, therefore, that the author's condemnation of anthropometrical methods for determining geographical varieties is too sweeping.

The scepticism with which the author regards the results of anthropometry lead him also to the conclusion that sameness of type is not a sufficient proof of common descent; that the latter is only proved if supported by historical and linguistic evidence. This opinion is open to serious objections. It is certainly true that it is impossible to determine by anatomical characteristics alone to what people a single individual belongs. But it is perfectly feasible to identify a series of individuals belonging to a certain people or district, if the series is sufficiently large. Dr. Ehrenreich, it would seem, has been misled by the fact that all types are variable and cannot be represented by a single typical individual to consider the whole task a hopeless one. Even though it is not possible to establish for a people a single anatomical type to which all individuals conform and which is characteristic of that people and no other, this does not prove that we cannot trace its genesis by means of a study of the various types constituting the people and their distribution among the people itself and its neighbors. The author acknowledges this fact to a certain extent when saying: "Whoever tries to rely in these investigations on physical characters alone will certainly be led astray. A consideration of the geographical point of view and of historical evidence will give much greater certainty to his conclusions." Here, as in the discussion of the races of man, the author strongly emphasizes the geographical point of view, and in this he agrees with F. Ratzel. He urges the necessity of considering the geographical probability of blood-relationship before generalizing from anatomical similarities. The considerations of this point of view, on which the reviewer has also repeatedly insisted, will certainly prevent anthropologists from forming rash conclusions and propounding extravagant theories.

But I do not believe that the introduction of linguistic considerations in the somatological problem will be found to be of advantage. It is true that wherever we find two tribes speaking affiliated languages there must have existed blood-relationship; but we have abundant proof showing that by infusion of foreign blood the anatomical types have changed to such an extent that the original type has been practically swamped by the intruders. Such is the case in North America among the Athapaskan tribes of the Southwest, among the widely scattered Shoshonean tribes, and in many other cases. The laws according to which anatomical types are preserved are not the same as those according to which languages are preserved, and for this reason we must not expect to find the results of classifications based on these two considerations to coincide. Dr. Ehrenreich seems to think that types are too variable to give any satisfactory basis for deductions of this character. But, notwithstanding the fact that certain anatomical features are easily

affected by the influence of environment, I cannot acknowledge that any proof of the transformation of the fundamental features of types exists.

In our investigations on the early history of mankind three methods are available, each directed to a certain series of phenomena—physical type, language, customs. These are not transmitted and do not develop in the same manner. The one persists when the other changes, but all may be made to contribute to the solution of the general problem. The study of the distribution of languages permits us to make nicer divisions and to follow historical changes in greater detail than that of the distribution of physical types. But often the latter give evidence in regard to phenomena which cannot be approached by linguistic methods. The distribution of the Alpine type of man in Europe, or that of the Sonoran type in North America, may be mentioned as instances of this kind. It would be absurd to state that in these cases similarity of type does not prove blood-relationship, because there is no linguistic evidence to support it. On the contrary, the physical investigation supplies evidence that cannot be gained by linguistic facts. The three methods mentioned above are all equally valuable, but since they do not refer to the same classes of facts it must not be expected that they will clear up the same incidents in the early history of mankind, but all may be utilized with equal advantage in the study of this subject.

In regard to the affinities of the American race to other races Dr. Ehrenreich seems to be inclined to consider it as equally closely related to the Asiatic and to the European races. He lays particular stress upon the proportions of the body and the form of the hair as distinguishing the Americans from the Asiatics. In this opinion he agrees to a certain extent with Brinton. It would seem to me that in determining the position of a race we should be guided by the morphology of its most generalized forms, namely of women and children. The far-reaching similarity between American and Asiatic children and women is very striking. They have in common the wide and rather low nose, the form of the eye and of the maxilla. The physiognomic similarity is so great that it would seem to be of greater weight than the variable proportions of the body which are much more subject to influences of environment.

FRANZ BOAS.

The Alternating-Current Circuit: An Introductory and Non-mathematical Book for Beginners and Students. By W. PERREN MAYCOCK. London, Whittaker & Co. 1897. 16mo. Pp. 97. Price, $1.00.

It is the author's purpose to convey some idea of single-phase alternating currents to the minds of those new to the subject, by means of plainly worded and non-mathematical language. In his preface (April, 1897) he states that the book forms the substance of a chapter in the forthcoming Volume II. of 'Electrical Lighting and Power Distribution.' With a thorough revision it would make an admirable chapter for such a book. Although the book is small, the reviewer appreciates the amount of labor that has been spent upon it in arranging the more important alternating current phenomena and discussing them in a manner suitable for non-mathematical beginners. The author has attempted to make his style simple and clear, successfully in the main, but with many startling lapses. What idea is conveyed to a reader (and he need not be a non-mathematical beginner) from the statement (p. 8), "The current in a given circuit is thus proportional to the distance traversed at each alternation by any given coulomb, *C*, multiplied by the number of alternations per second; so that if the current is kept constant, when the frequency is doubled, the path traversed by any given coulomb will be halved, and *vice versa*."

We note error as well as confusion; for example, on page 64 we are told that reactance varies directly as the inductance and the mutual induction. As a matter of fact, mutual induction in a case of a transformer diminishes the reactance; for the primary circuit of a transformer has less reactance when the secondary is loaded than when it is on open circuit. Again, it is stated (pages 64 and 85) that reactance depends directly upon the inductance and the *frequency*, and inversely upon the capacity. This is true when the current lags behind the

electromotive force, but when the circuit is in advance of the electromotive force an increase of frequency decreases the reactance.

The author points out that the terms virtual and effective are employed indiscriminately by some writers, but has been unsuccessful in his attempt to make the terms clear. The effective value of the E. M. F. is taken to be its component of direction of the current; the effective current is the component of current in the direction of the E. M. F., all of which is quite beyond criticism, unless it be one of words. 'Virtual value' is adopted to designate the square root of the mean square value and is properly explained to be the equivalent of a direct electromotive force or current which would produce the same effect either on an electrostatic voltmeter, or in heating. Thus, we may have occasion to refer to the virtual value or to the maximum value of any quantity, as of the impressed E. M. F., of the effective E. M. F., of the total current, or of the effective current. Although thus clearly giving a proper meaning to the term virtual, the author usually employs 'virtual E. M. F.' as synonymous with 'impressed E. M. F.,' and 'virtual current' as being the total or actual current which flows as distinguished from a particular component of it. Thus (p. 83), "In most circuits the impressed or virtual E. M. F. meets with an opposing E. M. F. of reactance, and the effective E. M. F. is something less than the virtual E. M. F. * * *" Also (p. 84), "That proportion of the current which can do useful work may be called the *effective current.* When there is no phase difference, the effective current is the same as the virtual current; but as the angle of lag or lead increases, so does the value of the effective as compared with the virtual current diminish." Again (p. 87), the author refers to 'impressed or virtual electromotive force.'

These two much abused words are likewise unnecessarily dragged in; thus (p. 64) we note 'virtual or effective resistance;' (pp. 89 and 93), effective watts,' the imputation being that we, might likewise have ineffective watts! Also (p. 94) we are told that the virtual watts put into a circuit may be far in excess of the actual power conveyed!

Throughout the book the author has used terms with meanings other than those he has assigned to them by definition.

These blemishes are serious ones. With thorough revision, the book will satisfactorily meet the admirable end the author had in view.

FREDERICK BEDELL.

Anleitung zur Mikrochemischen Analyse der wichtigsten organischen Verbindungen. Von H. BEHRENS, Professor an der Polytechnischen Schule zu Delft. Viertes Heft. Karbamide und Karbonsaeuren. Mit 94 Figuren im Text. Hamburg und Leipzig, Verlag von Leopold Voss. 1897. Pp 129. Mark 4.50.

In the first number of Professor Behrens' book the anthracene group, phenols, quinones, ketones and aldehydes were considered. The second number, treating of fibrous materials, was reviewed in this JOURNAL for January 15, 1897. The third number deals with aromatic amines, and with the present number continues the work satisfactorily. It should be remembered that Professor Behrens' work is the only textbook extant in this important field.

E. R.

Die Chemie im täglichen Leben. Von DR. LASSAR-COHN. Universitäts Professor zu Königsberg. Zweite Auflage. Hamburg und Leipzig, Verlag von Leopold Voss. 1897.

The first German edition of Professor Lassar-Cohn's book was fully reviewed in this JOURNAL for January 22, 1897, by Professor Orndorff. The appearance of a second German edition, and the success of Professor Pattison-Muir's English translation show the value of the book.

E. R.

SOCIETIES AND ACADEMIES.

THE NEBRASKA ACADEMY OF SCIENCES.

THE eighth annual meeting of the Academy was held at Lincoln on November 26th and 27th. On the first day the Presidential address was given by Dr. A. S. von Mansfelde, of Ashland, his subject being 'Some Practical Applications of Science.' It was devoted largely to a discussion of the alcohol question from the scientific and medical point of view in opposition to many untenable positions taken by advocates of total abstinence.

The paper by Dr. H. B. Ward on 'Factors in Civilized Life which modify the Abundance of Parasitic Animals' in man and domestic animals dealt with the advantage of modern methods of stall-feeding, watering from wells, cleanly modes of killing and packing. Dr. E. H. Barbour reported progress on the study of Dictomaceous Earths in Nebraska. Lymnæa, Physa and Planorbis occur as fossils. The beds are furnishing excellent material for packing engine boilers as a non-conductor of heat. 'The Flora of a Dried-up Mill Pond,' by C. J. Elmore, included a list of species and a classification of them according to habit and mode of distribution. Most of the species did not occur on the adjacent bank.

Dr. C. E. Bessey presented evidence of poisoning by *Rhus radicans* without direct contact and concludes that Dr. Pfaff's non-volatile toxicodendrol may not be the only poisonous principle present or that it must be sufficiently volatile to escape in hot moist air. Dr. Roscoe Pound presented observations on the 'Abundance of Certain Secondary Species in Prairie Formations,' and showed how it may be determined quantitatively by definite count, and how misleading any other estimate is apt to be. Professor F. W. Card presented 'Notes on Root Growth,' showing that whether roots were cut back much in planting or not the new roots in any case arose mainly from the base of the roots rather than from the callus at their tips, so that best results were obtained by leaving the roots without cutting back.

Mr. H. M. Benedict discussed the generic characters of the genus *Ichthyotænia* and described a new species. Professor G. D. Swezey reported upon experiments with color screens in astronomical photography, by which an ordinary visually corrected objective gave good results in photographing bright objects.

The evening was devoted to a lecture by Mr. N. H. Darton, of the U. S. Geological Survey, on 'Some Points in the Geology of Nebraska,' with lantern illustrations, and to a banquet for members and their wives.

The first paper on November 27th, by Dr. E. W. Davis, was a discussion of certain mathematical relations between the surfaces, edges and vertices of regular solids. Miss Carrie Barbour reported upon the history and results of the Morrill Geological Expeditions. Dr. E. H. Barbour reported upon 'A Second Nebraska Meteorite,' weighing six pounds; also upon 'Our Beds of Volcanic Ash,' which are found widely distributed in the State and which furnish a very pure polishing powder. They are found distinctly stratified and fossiliferous, showing aqueous deposition.

A paper by Dr. E. W. Davis on 'Karl Pearson's Researches on the Mathematical Theory of Evolution' showed how the theory of probabilities may be used in the discussion of biological and similar data. Mr. W. D. Hunter reported upon 'Additions to Professor Bruner's List of Nebraska Birds' and upon progress in compiling lists of insects of various orders for the State. Dr. Roscoe Pound reported upon the 'Progress of the Botanical Survey of Nebraska,' particularly upon the beginnings of a study of the phytogeographic as distinguished from the mere floral aspects of the subject. Dr. R. H. Wolcott presented a paper 'On the Genus *Atax*,' giving an account of generic characters, habits and a number of new species.

For lack of time the following papers were read by title only:

The Fern Allies of Franklin county, Neb.: E. M. Hussong.

The Peat Beds and Underlying Diatomaceous Deposits along Cedar Creek and Tributaries: J. P. Rowe.

On the Experimental Proof of Faraday's Theory of Electricity: Louis T. More.

Announcement of New Nebraska Fossils: Dr. E. H. Barbour.

Observations on the Concretions of the Pierre Shale: Carrie A. Barbour.

On the Taxonomy of the Nemathelminthes: Dr. H. B. Ward.

Oolitic Sands from the Dakota Cretaceous of Nebraska: Dr. E. H. Barbour.

Some Points in the Geology of Lincoln and its Environs: C. E. Fisher.

The following officers for the ensuing year were elected:

President, Dr. H. B. Ward, Lincoln; Vice-President, Dr. A. S. von Mansfelde, Ashland; Secretary-Treasurer, Professor G. D. Swezey, Lincoln; Custodian, Professor Lawrence Bruner, Lincoln.

The meeting was the most successful one in the history of the Academy, both in attendance and in the interest manifested. Its annual volume of Proceedings is now in press, and will be larger and more fully illustrated than usual.

G. D. Swezey,
Secretary.

BIOLOGICAL SOCIETY OF WASHINGTON—282ND MEETING, SATURDAY, NOVEMBER 20.

Mr. David White exhibited two specimens of Carboniferous shale from Lerkis-Bey, near Amasra, Asia Minor, on which are associated *Neuropteris Scheuchzeri* Hoffm., and *N. fimbriata* L., together with fragments of another *Neuropteris*, possibly *N. ovata* Hoffm., and two species of *Pecopteris*, one of which was *P. abbreviata* Brogn. Especial attention was called to the interesting circumstances that not only do these species appear to be identical in details with specimens similarly identified in the collection of the U. S. National Museum from the Lower Productive Coal Measures of Ohio and Pennsylvania, but that in this continent the species are also found in immediate association.

Dr. Erwin F. Smith exhibited a simple style of hypodermic syringe recently brought out by Baurch and Lamb.

Dr. Sternberg stated that it was identical in principle with one devised by himself when at Johns Hopkins University.

Professor O. F. Cook described 'A New Wingless Fly from Liberia,' stating that it was perhaps referable to the family Phoridæ, but that it represented a new genus to which the name *Wandolleckia* was given in honor of Dr. B. Wandolleck, Dipterist of the Berlin Museum. Wings, balancers and ocelli are lacking; the eyes are reduced to about forty hemispherical facets and the abdomen is membranous, the chitinous plates being rudimentary. The type *Wandolleckia achatinæ* inhabits the deep forests of Liberia, where it is found actively running about on *Achatina variegata* Roissy, the largest West African land snail. The genus may be related to *Puliciophora* Dahl, a wingless form from the Bismarck Archipelago, but is generically distinct in the much greater reduction of the abdominal plates and in the armature of the tarsi. The resemblance of both forms to fleas is probably merely superficial and has no phylogenetic implication.

Mr. V. K. Chestnut presented a paper entitled 'Some Recent Cases of Mushroom Poisoning.' The symptoms of ten cases collected by the Botany Division of the U. S. Department of Agriculture during the past year were given. Two of these were fatal to four individuals. The minor cases were caused by *Clitocybe illudens*, *Russula emetica*, *Boletus subtomentosus*, *Agaricus morganii*, a species of *Clavaria*, and the puff ball, *Lycoperdon giganteum* Batsch. One case of poisoning by the last-named species was especially noted because, although the fungus was unquestionably fresh and was properly cooked, the symptoms were very marked. The two fatal cases reported were caused by the fly amanita (*Amanita muscaria* (*L.*) *Fr.*) and the death cup (*Amanita phalloides* (L.)Fr.). It was conclusively shown by photographs, drawings and specimens that the former caused the death of Count de Vecchj in Washington on November 10, 1897, it having been mistaken for the orange amanita (*Amanita cæsarea*). The case was, however, complicated with apoplexy. Another gentleman who ate some of the same fungus was saved by repeated doses of $\frac{1}{100}$–$\frac{1}{50}$ of a grain of atropine, this being an almost perfect physiological antidote to the effects of muscarine. The seeds of Jimson weed (*Datura strammonium*) could also be used to advantage in such cases. Freshly ignited charcoal is valuable for its physical properties in absorbing the poison, and an alkaline solution of the permanganate of potash is in some cases useful as a chemical antidote. There is no antidote against the effects of phallin, the toxalbumin which causes death in *Amanita phalloides* poisoning, but in severe cases the transfusion of salt water or fresh blood is recommended. The action of the poison from the two amanitas is altogether different. Muscarine paralyzes the heart and produces marked stupor, while phallin dissolves the red blood corpuscles, causes a gradual collapse and generally leaves the brain unaffected.

Dr. Erwin F. Smith spoke on Bacterial Diseases of Plants, taking for his text certain misstatements in Dr. Alfred Fischer's recent *Vorlesungen über Bakterien.* At least ten diseases of plants are now known to be due to

bacteria. These are about equally divided between Europe and America, and there is no excuse for ignorance concerning them.

F. A. LUCAS, *Secretary.*

ZOOLOGICAL CLUB, UNIVERSITY OF CHICAGO. OCTOBER, 1897.

Two Cases of Mimicry.—The results of some observations on the mimetic habits of the Syrphid flies of the genus *Spilomyia* were presented. *S. fusca*, Leow, which is dull black-banded and spotted with yellowish white, was frequently seen flying about in the shrubbery and feeding on the honey of some golden-rods that had sprung up in a clearing in the pine woods (Price Co., Wis.). This Syrphid resembles in size, form, coloration and movements *Vespa maculata* and a smaller allied species of wasp, and was observed to occur in the same places and at the same time as these Hymenopterous models. A large female of *S. fusca* was masticated and found to have an agreeable flavor, the alimentary tract of the insect being full of honey in this instance. Therefore, warning colors are associated with the absence of disagreeable smell and taste, as the generally accepted theory of mimicry requires. In the same locality *Spilomyia quadrifasciata*, Say, was less common than *S. fusca.* It strikingly resembles the species of *Odynerus* (*O flavipes* and *O. foraminatus*), which also frequent the flowers of the golden-rods. Both insects are black, spotted and banded with bright yellow, the black predominating. The genus *Spilomyia* includes also a third group of mimics, which, like *S. liturata*, Williston, closely resemble the 'yellow-jacket' wasps (*V. germanica*, etc.). In these flies the deep yellow bands are broader and more numerous and the black coloring more restricted than in *S. fusca* and *S. quadrifasciata.*

W. M. WHEELER.

Secondary Mesoblast in the Mollusca.—Secondary mesoblast was first found in the mollusks in the lamellibranch Unio by Dr. F. R. Lillie. This secondary mesoblast was found to arise asymmetrically from a cell of the second generation of ectomeres on the left side of the egg. It subsequently becomes disposed symmetrically on both sides of the egg, apparently by a migration of some of the cells, and is mainly employed in the formation of the larval adductor muscle.

Later, secondary mesoblast was discovered in the gasteropod crepidula by Dr. Conklin. It was found to arise from the second generation of ectomeres, as in Unio, but from three quadrants instead of one, and at a much later stage of develepment than in the form studied by Lillie.

The secondary mesoblast in Physa, according to Wierzejski, and in Planorbis, according to my own observations, has a still different origin, since it arises from cells of the third generation of ectomeres on the anterior side of the egg. Its origin is symmetrical, as it arises from the two anterior quadrants of the third quartette, which lie on either side of the median plane. The divisions of the cells in the third quartette in Planorbis agree very closely with those of Physa until a late period of cleavage. In both forms the first division of the cells of the third quartette is radial ; at the next division both the upper and lower cells in the two anterior quadrants divide horizontally into equal parts. The next cleavage in the anterior quadrants is the unequal division of the lower pair of cells, each cell giving off a small cell toward the vegetal pole. In both Physa and Planorbis the upper pair of cells resulting from this last cleavage contain the secondary mesoblast. In Planorbis these cells, after dividing almost horizontally, sink into the segmentation cavity and finally lose connection with the wall of the blastula. Whether these cells are entirely converted into secondary mesoblast in Physa, as in Planorbis, appears uncertain from Wierzejski's account.

S. J. HOLMES.

Dr. Whitman gave an account of his observations concerning the results of crossing the brown and the white varieties of ring-dove, and Dr. Watase read a paper entitled 'Protoplasmic Contractility and Phosphorescence.'

During the month the following reviews of recent papers were also given: 'The Embryology of Crepidula' (Conklin), A. L. Treadwell ; 'Recent Literature on Spermatogenesis' (Meves and Hermann), W. H. Packard ; 'Structure of Nermertean Nerve-cells' (Montgomery), G. W. Hunter.

*SIGNALLING THROUGH SPACE WITHOUT WIRES.**

SCIENCE has conferred one great benefit on mankind. It has supplied us with a new sense. We can now see the invisible, hear the inaudible and feel the intangible. We know that the universe is filled with a homogeneous continuous elastic medium which transmits heat, light, electricity and other forms of energy from one point of space to another without loss. The discovery of the real existence of this 'ether' is one of the great scientific events of the Victorian era. Its character and mechanism are not yet known by us. All attempts to 'invent' a perfect ether have proved beyond the mental powers of the highest intellects. We can only say with Lord Salisbury that the ether is the nominative case to the verb 'to undulate.' We must be content with a knowledge of the fact that it was created in the beginning for the transmission of energy in all its forms, that it transmits these energies in definite waves and with a known velocity, that it is perfect of its kind, but that it still remains as inscrutable as gravity or life itself.

Any disturbance of the ether must originate with some disturbance of matter. An explosion, cyclone or vibratory motion may occur in the photosphere of the sun. A disturbance or wave is impressed on the

* An address given before the Royal Institution by W. H. Preece, Esq., C.B., F.R.S., M.Inst.C.E.

ether. It is propagated in straight lines through space. It falls on Jupiter, Venus, the Earth and every other planet met with in its course, and any machine, human or mechanical, capable of responding to its undulations indicates its presence. Thus the eye supplies the sensation of light, the skin is sensitive to heat, the galvanometer indicates electricity, the magnetometer indicates disturbances in the earth's magnetic field. One of the greatest scientific achievements of our generation is the magnificent generalization of Clerk-Maxwell that all these disturbances are of precisely the same kind, and that they differ only in degree. Light is an electromagnetic phenomenon, and electricity in its progress through space follows the laws of optics. Hertz proved this experimentally, and few of us who heard it will forget the admirable lecture on 'The Work of Hertz' given in this hall by Professor Oliver Lodge three years ago.*

By the kindness of Professor Silvanus Thompson, I am able to illustrate wave transmission by a very beautiful apparatus devised by him. At one end we have the *transmitter* or oscillator, which is a heavy suspended mass to which a blow or impulse is given, and which, in consequence, vibrates a given number of times per minute. At the other end is the *receiver*, or resonator, timed to vibrate to the same period. Connecting the two together is a row of leaden balls suspended so that each ball gives a portion of its energy at each oscillation to the next in the series. Each ball vibrates at right angles to or athwart the line of propagation of the wave, and as they vibrate in different phases you will see that a wave is transmitted from the transmitter to the receiver. The receiver takes up these vibrations and responds in sympathy with the transmitter. Here we have a visible illustration of that which is absolutely invisible. The wave you see differs from a wave of light or of electricity only in its length or in its frequency. Electric waves vary from units per second in long submarine cables to millions per second when excited by Hertz's method. Light waves vary per second between 400 billions in the red to 800 billions in the violet, and electric waves differ from them in no other respect. They are reflected, refracted and polarized; they are subject to interference, and they move through the ether in straight lines with the same velocity, viz., 186,400 miles per second—a number easily recalled when we remember that it was in the year 1864 that Maxwell made his famous discovery of the identity of light and electric waves.

* This is published in an enlarged and useful form by *The Electrician* Printing and Publishing Company.—W. H. P.

Electric waves, however, differ from light waves in this, that we have also to regard the direction at right angles to the line of propagation of the wave. The model gives an illustration of that which happens along a *line of electric force;* the other line of motion I speak of is a circle around the point of disturbance, and these lines are called *lines of magnetic force.** The animal eye is tuned to one series of waves; the 'electric eye,' as Lord Kelvin called Hertz's resonator, to another. If electric waves could be reduced in length to the forty-thousandth of an inch we should see them as colors.

One more definition, and our ground is cleared. When electricity is found stored up in a potential state in the molecules of a dielectric like air, glass or gutta-percha the molecules are strained; it is called a *charge*, and it establishes in its neighborhood *an electric field.* When it is active, or in its kinetic state in a circuit, it is called a *current.* It is found in both states, kinetic and potential, when a current is maintained in a conductor. The surrounding neighborhood is then found in a state of stress, forming what is called a *magnetic field.*

* *Vide* Fig. 4.

In the first case the charges can be made to rise and fall, and to surge to and fro with rhythmic regularity, exciting *electric waves* along each line of electric force at very high frequencies, and in the second case the currents can rise or alternate in direction with the same regularity—but with very different frequencies—and originate *electro-magnetic waves* whose wave fronts are propagated in the same direction.

The first is the method of Hertz, which has recently been turned to practical account by Mr. Marconi, and the second is the method which I have been applying, and which for historical reasons I will describe to you first.

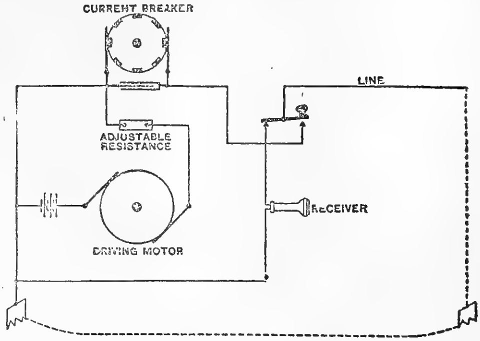

FIG. 1. Diagram of connections of Mr. Preece's system.

In 1884 messages sent through insulated wires buried in iron pipes in the streets of London were read upon telephone circuits erected on poles above the housetops, 80 feet away. Ordinary telegraph circuits were found in 1885 to produce disturbances 2,000 feet away. Distinct speech by telephone was carried on through one-quarter of a mile, a distance that was increased to $1\frac{1}{4}$ miles at a later date. Careful experiments were made in 1886 and 1887 to prove that these effects were due to pure electro-magnetic waves, and were entirely free from any earth conduction. In 1892 distinct messages were sent across a portion of the Bristol Channel between Penarth and Flat Holm, a distance of 3.3 miles.

Early in 1895 the cable between Oban and the Isle of Mull broke down, and as no ship was available for repairing and restoring communication, communication was established by utilizing parallel wires on each side of the Channel and transmitting signals across this space by these electro-magnetic waves.

The apparatus (Fig. 1) connected to each wire consists of:

(*a*) A rheotome or make and break wheel, causing about 260 undulations per second in the primary wire.

(*b*) An ordinary battery of about 100 Leclanché cells, of the so-called dry and portable form.

(*c*) A Morse telegraph key.

(*d*) A telephone to act as receiver.

(*e*) A switch to start and stop the rheotome.

Good signals depend more on the rapid rise and fall of the primary current than on the amount of energy thrown into vibration. Leclanché cells give as good signals at 3.3 miles distant as $2\frac{1}{2}$ H.P. transformed into alternating currents by an alternator, owing to the smooth sinusoidal curves of the latter. 260 vibrations per second give a pleasant note to the ear, easily read when broken up by the key into dots and dashes.

In my electro-magnetic system two parallel circuits are established, one on each side of a channel or bank of a river, each circuit becoming successively the primary and secondary of an induction system, according to the direction in which the signals are being sent. Strong alternating or vibrating cur-

rents of electricity are transmitted in the first circuit so as to form signals, letters and words in Morse character. The effects of the rise and fall of those currents are transmitted as electro-magnetic waves through the intervening space, and if the secondary circuit is so situated as to be washed by these etheral waves, their energy is transformed into secondary currents in the second circuit, which can be made to affect a telephone and thus to reproduce the signals. Of course, their intensity is much reduced but still their presence has been detected, though five miles of clear space have separated the two circuits.

Such efforts have been known scientifically in the laboratory since the days of Faraday and of Henry, but it is only within the last few years that I have been able to utilize them practically through considerable distances. This has been rendered possible through the introduction of the telephone.

Last year (August, 1896) an effort was made to establish communication with the North Sandhead (Goodwin) lightship. The apparatus used was designed and manufactured by Messrs. Evershed and Vignoles, and a most ingenious relay to establish a call was invented by Mr. Evershed. One extremity of the cable was coiled in a ring on the bottom of the sea, embracing the whole area over which the lightship swept while swinging to the tide, and the other end was connected with the shore. The ship was surrounded above the water line with another coil. The two coils were separated by a mean distance of about 200 fathoms, but communication was found to be impracticable. The screening effect of the sea water and the effect of the iron hull of the ship absorbed practically all the energy of the currents in the coiled cable, and the effects on board, though perceptible, were very trifling—too minute for signalling. Previous experiments had failed to show the extremely rapid rate at which energy is absorbed with the depth or thickness of sea water. The energy is absorbed in forming eddy currents. There is no difficulty whatever in signalling through 15 fathoms. Speech by telephone has been maintained through 6 fathoms. Although this experiment has failed through water, it is thoroughly practicable through air to considerable distances where it is possible to erect wires of similar length to the distance to be crossed on each side of the channel. It is not always possible, however, to do this, nor to get the requisite height to secure the best effect. It is impossible on a lightship and on rock lighthouses. There are many small islands—Sark, for example—where it cannot be done.

In July last Mr. Marconi brought to England a new plan. My plan is based entirely on utilizing electro-magnetic waves of very low frequency. It depends essentially on the rise and fall of *currents* in the primary wire. Mr. Marconi utilizes electric or Hertzian waves of very high frequency, and they depend upon the rise and fall of electric force in a sphere or spheres. He has invented a new relay which, for sensitiveness and delicacy, exceeds all known electrical apparatus.

The peculiarity of Mr. Marconi's system is that, apart from the ordinary connecting wires of the apparatus, conductors of very moderate length only are needed, and even these can be dispensed with if reflectors are used.

The Transmitter.—His transmitter is Professor Righi's form of Hertz's radiator (Fig. 2).

Two spheres of *solid* brass, 4 inches in diameter (A and B), are fixed in an oil-tight case D of insulating material, so that a hemisphere of each is exposed, the other hemisphere being immersed in a bath of vaseline oil. The use of oil has several

advantages. It maintains the surfaces of the spheres electrically clean, avoiding the frequent polishing required by Hertz's exposed balls. It impresses on the waves excited by these spheres a uniform and con-

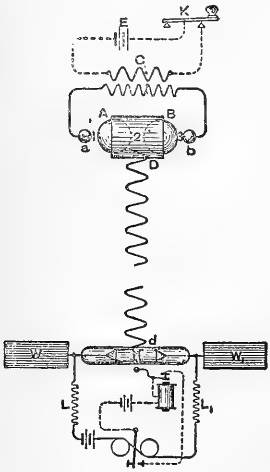

FIG. 2. Diagram of the Marconi Apparatus.

stant form. It tends to reduce the wave lengths; Righi's waves are measured in centimetres, while Hertz's were measured in metres. For these reasons the distance at which effects are produced is increased. Mr. Marconi uses generally waves of about 120 centimetres long. Two small spheres, *a* and *b*, are fixed close to the large spheres, and connected each to one end of the secondary circuit of the 'induction coil' C, the primary circuit of which is excited by a battery E, thrown in and out of circuit by the Morse key K. Now, whenever the key K is depressed sparks pass between 1, 2 and 3, and since the system A B contains a capacity and electric inertia, oscillations are set up in it of extreme rapidity. The line of propagation is D *d*, and the frequency of oscillation is probably about 250 millions per second.

The distance at which effects are produced with such rapid oscillations depends chiefly on the energy in the discharge that passes. A 6-inch spark coil has sufficed through 1, 2, 3, up to 4 miles, but for greater distances we have used a more powerful coil—one emitting sparks 20 inches long. It may also be pointed out that this distance increases with the diameter of the spheres A and B, and it is nearly doubled by making the spheres solid instead of hollow.

The Receiver.—Marconi's relay (Fig. 2) consists of a small glass tube four centimeters long, into which two silver pole-pieces are tightly fitted, separated from each other by about half a millimeter—a thin space which is filled up by a mixture of fine nickel and silver filings, mixed with a trace of mercury. The tube is exhausted to a vacuum of 4 mm., and sealed. It forms part of a circuit containing a local cell and a sensitive telegraph relay. In its normal condition the metallic powder is virtually an insulator. The particles lie higgledy-piggledy, anyhow, in disorder. They lightly touch each other in an irregular method, but when electric waves fall upon them they are 'polarized,' order is installed. They are marshalled in serried ranks; they are subject to pressure—in fact, as Professor Oliver Lodge expresses it, they 'cohere'—electrical contact ensues and a current passes. The resistance of such a space falls from infinity to about five ohms. The electric resistance of Marconi's relay—that is, the resistance of the thin disc of loose powder—is practically infinite when it is in its normal or disordered condition. It is, then, in fact, an insulator. This resistance drops sometimes to five ohms, when the absorption of the electric waves by it is intense. It, therefore, becomes a conductor. It may be, as suggested by

Professor Lodge, that we have in the measurement of the variable resistance of this instrument a means of determining the intensity of the energy falling upon it. This variation is being investigated both as regards the magnitude of the energy and the frequency of the incident waves. Now such electrical effects are well known. In 1866 Mr. S. A. Varley introduced a lightning protector constructed like the above tube, but made of boxwood and containing powdered carbon. It was fixed as a shunt to the instrument to be protected. It acted well, but it was subject to this coherence, which rendered the cure more troublesome than the disease, and its use had to be abandoned. The same action is very common in granulated carbon microphones like Hunting's, and shaking has to be resorted to, to decohere the carbon particles to their normal state. M. E. Branly (1890) showed the effect with copper, aluminium and iron filings. Professor Oliver Lodge, who has done more than any one else in England to illustrate and popularize the work of Hertz and his followers, has given the name 'coherer' to this form of apparatus. Marconi 'decoheres' by making the local current very rapidly vibrate a small hammer head against the glass tube, which it does effectually, and in doing so makes such a sound that reading Morse characters is easy. The same current that decoheres can also record Morse signals on paper by ink. The exhausted tube has two wings which, by their size, tune the receiver to the transmitter by varying the capacity of the apparatus.* Choking coils prevent the energy escaping. The analogy to Professor Silvanus Thompson's wave apparatus is evident. Oscillations set up in the transmitter fall upon the receiver tuned in sympathy with it, coherence follows, currents are excited and signals made.

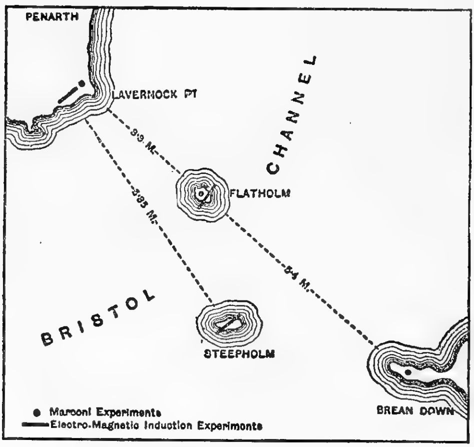

FIG. 3. Map of locality where the experiments were carried out.

In open clear spaces within sight of each other nothing more is wanted, but when obstacles intervene and great distances are in question height is needed; tall masts, kites and balloons have been used. Excellent signals have been transmitted between Penarth and Brean Down, near Weston-super-Mare, across the Bristol Channel, a distance of nearly nine miles (Fig. 3). [The system was here shown in operation.]

Mirrors also assist and intensify the effects. They were used in the earlier experiments, but they have been laid aside for the present, for they are not only expensive to make, but they occupy much time in manufacture.

* The period of vibration of a circuit is given by the equation $T = 2\pi \sqrt{KL}$, so that we have simply to vary either the capacity K or the so-called 'self-induction' L to tune the receiver to any frequency. It is simpler to vary K.

It is curious that hills and apparent obstructions fail to obstruct. The reason is probably the fact that the lines of force escape these hills. When the ether is entangled in matter of different degrees of inductivity the lines are curved, as in fact they are in light. Fig 4 shows how a hill is vir-

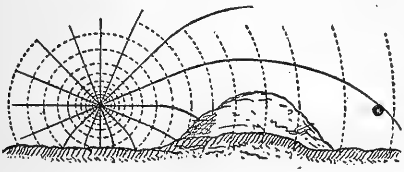

FIG. 4. Diagram illustrating the way in which hills are bridged by the electric waves.

tually bridged over by these lines, and consequently some electric waves fall on the relay. Weather seems to have no influence —rain, fogs, snow and wind avail nothing.

The wings in Fig. 2 may be removed. One pole can be connected with earth, and the other extended up to the top of the mast, or fastened to a balloon by means of a wire. The wire and balloon or kite covered with tin foil becomes the wing. In

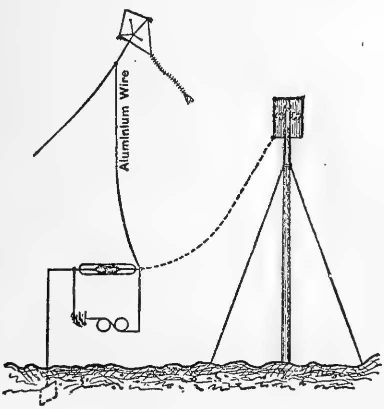

FIG. 5. Diagram of Marconi connections when using pole or kite.

this case one pole of the transmitter must also be connected with the earth. This is shown by Fig. 5.

There are some apparent anomalies that have developed themselves during the experiments. Mr. Marconi finds that his relay acts even when it is placed in a perfectly closed metallic box. This is the fact that has given rise to the rumor that he can blow up an iron-clad ship. This might be true if he could plant his properly tuned receiver in the magazine of an enemy's ship. Many other funny things could be done if this were possible. I remember in my childhood that Captain Warner blew up a ship at a great distance off Brighton. How this was done was never known, for his secret died shortly afterwards with him. It certainly was not by means of Marconi's relay.

The distance to which signals have been sent is remarkable. On Salisbury Plain Mr. Marconi covered a distance of four miles. In the Bristol Channel this has been extended to over eight miles, and we have by no means reached the limit. It is interesting to read the surmises of others. Half a mile was the wildest dream.*

It is easy to transmit many messages in any direction at the same time. It is only necessary to tune the transmitters and receivers to the same frequency or 'note.' I could show this here, but we are bothered by reflection from the walls. This does not happen in open space. Tuning is very easy. It is simply necessary to vary the capacity of the receiver, and this is done by increas-

* "Unfortunately at present we cannot detect the electro-magnetic waves more than 100 feet from their source." Trowbridge, 1897, *What is Electricity*, p. 256.

"I mention 40 yards because that was one of the first out-of-door experiments, but I should think that something more like half a mile was nearer the limit of sensibility. However, this is a rash statement not at present verified." Oliver Lodge, 1894, *The Work of Hertz*, p. 18.

ing the length of the wings W in Fig. 2. The proper length is found experimentally close to the transmitter. It is practically impossible to do so far away.

It has been said that Mr. Marconi has done nothing new. He has not discovered any new rays; his transmitter is comparatively old; his receiver is based on Branly's coherer. Columbus did not invent the egg, but he showed how to make it stand on its end, and Marconi has produced from known means a new electric eye more delicate than any known electrical instrument, and a new system of telegraphy that will reach places hitherto inaccessible. There are a great many practical points connected with this system that require to be threshed out in a practical manner before it can be placed on the market, but enough has been done to prove its value, and to show that for shipping and lighthouse purposes it will be a great and valuable acquisition.

CHARACTERS, CONGENITAL AND ACQUIRED.

The characters of a living organism, plant or animal, are usually grouped by biologists under two heads, the congenital, or inborn, and the acquired. But hitherto no systematic attempt has been made to give precision to these terms—to define precisely what we mean by them, and in the case of any particular organism to ascertain exactly which of its characters are inborn and which acquired. I know nothing in the whole range of science which promises to the thinker more immediate and solid results than this strangely neglected field of investigation. For example, had it received the attention it deserved, it is probable that the great controversy as to the transmissibility of acquired traits between the Neo-Lamarckian and Darwinian schools would long ago have ceased, since only after it has been definitely determined whether this or that trait is inborn or acquired can the fact of its transmissibility or non-transmissibility profitably be used as an argument for or against the Lamarckian doctrine. This precisely the disputants have not done—an assertion I shall justify presently. To deal with my subject adequately one should have the powers of a Darwin or a Herbert Spencer; if, however, I can contrive to direct attention to it I shall be well content.

An inborn variation may be defined as one which arises in an organism owing to changes previously produced by the action of the environment in the germ cell (or pair of germ cells) whence it sprang. As inborn variations are admittedly transmissible, all inborn characters must have arisen thus in the ancestry* and, deductively, it must follow, as, indeed, may easily be proved inductively,† that changes in a germ cell tend to be reproduced in its descendant germ cells, for which reason the organisms that arise from them tend also to reproduce the inborn variations of the parent organism.

An acquired character may be defined as one which arises in the organism owing to changes produced by the action of the environment, not on the germ cell, but on the somatic cells derived from it. If acquired modifications are transmissible, then changes in the somatic cells must tend so to modify the germ cells associated with them that, as a consequence, the organisms they proliferate into tend to reproduce, as inborn characters, the *particular* variations which were acquired by the parent organism.

* That is, if we accept the Neo-Darwinian doctrine.

† All unicellular organisms are germ cells; that is, they are all capable of continuing the species. When modified by the action of the environment they tend to transmit their modifications to descendant organisms, as has been abundantly proved by bacteriologists. A striking example is afforded by the organism which produces small-pox. If transferred to the cow it becomes so modified in the new environment that it ever afterwards causes in man, not small-pox, but cow-pox.

I dare say that the above definitions will be objected to by some of my readers, but I am in hopes that, on consideration of what follows, the majority will assent to them as indicating pretty correctly what we really mean by the terms 'inborn' and 'acquired.' I do not here propose to discuss the question as to whether acquired modifications are transmissible; I have done it at length elsewhere, and my present object is rather to differentiate accurately between the acquired and the congenital, and to ascertain the parts played by them respectively in the organic world. I may, in passing, however, notice one or two points which have been frequent sources of confusion and the consideration of which may help to bring the meaning I intend my definitions to bear clearly before the mind.

It has often been maintained by Neo-Lamarckians that important modifications in the soma (*e. g.*, the effects of disease) *must* affect the associated germ cells, and that therefore acquired modifications *must*, to some extent, be transmissible.* They miss the point at issue. It is not denied that changes in the germ's environment (*i. e.*, in the body of the parent) may result in modifications in the organism into which the germ subsequently proliferates, but it is strenuously denied that acquired modifications in the parent tend specially so to modify the germ as to cause the organism into which it subsequently proliferates to reproduce congenitally the particular modification which the parent acquired. Again, supposing some cause (*e. g.*, disease) produced a modification (*e. g.*, cavities in the lungs) in the soma and that subsequently, in the absence of the cause, the offspring developed the modification; even this would not constitute an absolute proof of the Lamarckian doctrine, though it would raise a presumption in favor of it. For it must be remembered that it is not asserted that a force acting on an organism cannot produce such a change in the germ as will cause the organism into which it develops to exhibit a variation similar to the modification produced by the force in the parent, but that it is asserted that this coincidence, this mere coincidence, must, from the nature of the case, be extremely rare, so very rare that, as factors in evolution, such apparent, but only apparent, transmission of acquired traits may practically be ignored. Only after it had been shown that clear and indubitable cases of reproduction by the offspring of the parents' modification were not uncommon in nature could the truth of the Lamarckian doctrine be accepted as proven.

Watching the multiplication of an infusorian (*Stylonychia Pustulata*), Maupas observed that, after two of these had conjugated, the resulting fertilized cell divided and redivided many times without conjugation again occurring, but that if, after a certain pretty definite number of cell-divisions, conjugation did not again occur, the race ultimately died out. He found, moreover, that the descendants of a conjugated pair did not conjugate among themselves, but only with the descendants of another conjugated pair. All this is the rule among higher plants and animals. The ovum and the sperm are unicellular organisms. After conjugation they divide and redivide many times without conjugation again occurring among the descendant cells. But these, like the infusorians, if they do not conjugate, ultimately die out. Most of them (*i. e.*, the somatic cells) are incapable of conjugation, while such of them as are capable of conjugation (*i. e.*, the germ cells) conjugate only with cells

* "The germ is a unicellular organism and therefore it should be modifiable in accordance with its environment. Such environment would be different in the body of a sedentary clerk and a hard-working agricultural laborer, and on this hypothesis the offspring in these cases would be different." (S. S. Buckman, *Natural Science*, March, 1897, p. 189.)

from another body (*i. e.*, cell-family). There are, as is well known, exceptions to the above; unending reproduction may occur without conjugation, as among such plants as are propagated by slips or suckers, and self-fertilization also occurs, but the general rule is as I have stated. A multicellular plant or animal in the successive stages of its development is therefore the homologue, not of the remote ancestral unicellular organism, but of all those successive generations of unicellular organisms which intervene between one act of conjugation and the next.

Unlike the cell descendants of a conjugated unicellular organism, the cell-descendants of a conjugated germ differ from it, and from one another, in that they undergo differentiation along certain definite lines (into nerve, muscle, bone, etc.), the germ cells being so specialized that the cell-communities which spring from them are very like the cell-community of which they were cell-members, for which reason a man, for instance, is like his parent. Moreover, the cell-descendants of the conjugated germ differ from the cell-descendants of the conjugated unicellular organism in that they remain adherent, and in that, in different lines of descent, they multiply at different though definite rates. Did the cell-descendants of the germ all multiply at an equal rate, a solid spherical mass of cells would, of course, result; whereas, owing to differences in their rates of multiplication, the shape of multicellular plants and animals are irregular (*i. e.*, not spherical). But, though these rates of multiplication in different lines of descent are pretty definite in every species of plant and animal, they differ widely in different species, whence arise differences in shape betwixt one species and another. An ox, for instance, differs in shape from a man because in it the cells in different lines of descent do not multiply at the same rate as in the man.

We cannot doubt that, when first multicellular organisms were evolved from unicellular, all the cells constituting the mass were morphologically and physiologically similar, and that, therefore, like the ancestral unicellular organism, every cell was capable of performing all the functions of life—food-getting, locomotion, reproduction of the race, etc. Later, as a result of natural selection, differentiation appeared among the adherent cells of the community, some taking on one function and some another, till at length a high degree of differentiation resulted, and the reproduction of the race was delegated to the germ cells.

As I have already indicated, among the unicellular organisms every cell is a germ cell, and as such is capable of continuing the race. Among low multicellular organisms this power persists in many cells, and the environment decides whether it shall be exercised or not; thus, if almost any fragment of a sponge be bedded out it will proliferate into a complete individual. It persists longer in plants than in animals; thus from a fragment of begonia leaf may arise an entire individual capable of continuing the race; the cells are being turned from their original destiny by a change in the environment. But among the higher plants this power of reproducing the entire individual by means of cells other than germ cells, or what may normally proliferate into germ cells, is very exceptional. All that commonly persists is the power of reproducing from such fragments of the complete organism as contain cells, which might normally proliferate into germ cells, the parts wanting to render the fragment a complete organism. Thus a geranium slip (for instance) contains cells which normally (*i. e.*, when the branch remains part of the plant) proliferate into germ cells; if this branch be bedded out as a slip it produces the roots which are needed to convert it into a complete organism of its

species. Here germ cells are not produced from cells not destined to that purpose as in the begonia leaf, but lost parts are reproduced by what may be termed (and in fact is) an exaggerated process of healing. In other plants the power of reproducing lost parts is present in a much smaller scale, and only comparatively trifling injuries are healed; *i. e.*, a small fragment cannot reproduce the whole, though the whole can reproduce lost fragments. Among animals, owing to the greater specialization of the cells and the more complex condition under which they live, this power of reproducing lost parts is present in general to a much less extent than among plants. Low in the scale, as we see, a fragment of sponge, for instance, can reproduce the whole. Higher in the scale, a starfish can reproduce a ray, a lobster a claw, a lizard its tail, and so forth, but none of these parts can reproduce the whole; that is done solely by germ cells. Higher yet, as among birds and mammals, the power of reproducing lost parts is comparatively very trifling; important and complex parts cannot be restored. Wounds and mutilations are healed, but, if serious, very imperfectly, for only scar tissue replaces the normal tissues which were lost.

We see, then, that the reproduction of lost parts, whether it be on a very great and perfect scale, as when a fragment reproduces a whole as in a sponge, or whether it be on a very small and imperfect scale, as when a wound is healed in one of the higher animals, is a process of the same order. Now, we speak of a scar in man, for example, as an acquired character; but who would dream of speaking of all that which is reproduced by the fragment of a sponge or a begonia leaf as a character acquired by the fragment. Moreover, when one of the higher animals is mutilated, as when a dog loses his tail, we lump together both the mutilation and the tissue with which the lost part is replaced (*i. e.*, the scar) as a single acquired character. But, even if we should agree for convenience to regard the scar as an acquired character, surely the mutilation ought not to be so designated, but should rather be termed (as I venture to suggest) *an enforced* character. We see, moreover, that the power of reproducing lost parts to a greater or less extent persists throughout organic nature, but that this power is vastly greater low in the scale than higher. In other words, if we agree to regard such reproductions as acquired, observation proves that the power of acquiring them is very much greater low in the scale (*e. g.*, sponge) than it is higher (*e. g.*, man).

On the other hand, there is another class of acquired characters—*perhaps the only class to which the term should properly be applied*—the power of acquiring which is greatest among the highest animals, and apparently is little or not at all present among the lower animals, nor in the whole of the plant world. I speak of such characters as arise as a result of exercise and use, as, for instance, the increased muscular power of an athlete. In the plant world no characters can, of course, be acquired as a response to the stimulation of exercise and use. Plants, therefore, of necessity, attain their full development in the absence of all other stimulation than such as is supplied by sufficient food and warmth. Of such plant-like animals as sponges the same also, of necessity, is true. It is true, with possible exceptions, even of such active animals as insects. Thus a pupa may develop into a perfect insect while lying quiescent. The lower vertebrates, such as fish and reptiles, have also little or no power of developing in response to the stimulation of use and exercise; apparently they are able to grow into normal, adult animals in its absence; thus if a tadpole finds its way through a crevice into a small cavity, and is able to obtain sufficient food, it develops

into a normal frog, though it leads a purely vegetative life. Higher yet in the scale among birds and mammals, and most of all among the highest mammals, the animal attains its full development, as regards many structures, only in response to the stimulation of exercise and use; thus, for instance, if the limb of an infant be locked by paralysis or by a joint disease so that it cannot be used it does not develop into an adult limb. Now, if a 'normal' man takes a more than ordinary amount of exercise he gets a more than ordinary development of various structures, as happens in the case of the blacksmith's arm. This extra development is regarded by biologists as 'abnormal' and is rightly termed 'acquired.' But, as we see, the 'normal' degree of development is attained only as a response to exercise (*i. e.*, stimulation), similar in kind though less in amount. *Therefore, it is clear that the full development of the normal adult arm, as well as many other important structures, is acquired*, differing in this from eyes, ears, teeth, nails, etc., which are wholly inborn, and do not owe their development in the least to use and exercise. In fact, on consideration, I think it will be found that adult man differs physically from the infant almost wholly in characters which are acquired, not in those which are inborn. In teeth, hair, skull-bones, genital organs, and in some other respects, he differs from the infant as regards inborn characters; but as regards almost all the structures of the trunk and limbs, and most of those of the head, the difference is in characters which have been acquired by the adult as a response to the stimulation of exercise and use. Thus the limbs develop wholly in response to use, the heart and arteries develop within certain limits in proportion to the strain put on them, as also do the lungs and their accessory muscles, as well as the bony attachments of the latter. The muscles, arteries, nerves, etc., of the head and neck also develop in response to the same stimulation. Moreover, the normal standard of development is maintained only as a response to this stimulation (*i. e.*, use, exercise), for example, when not used, the muscles with their coördinated structures atrophy and tend to disappear, as in the case of a paralyzed limb. It may be added that it is probable that even the infantile standard of development is, to some extent, acquired under the stimulus of fœtal movements in utero.

In upholding the doctrine of the transmissibility of acquired modifications much stress has been laid by Mr. Herbert Spencer and others on the exquisite coördination of the multitudinous parts of the high animal organism. They maintain that this coördination affords decisive proof of the Lamarckian theory, the line of argument being as follows: It is not probable that all the many structures of a high animal can ever have varied favorably together (as compared to the parent) in any individual animal. It is unbelievable that they can all have varied favorably generation after generation in a line of individuals. A chain is only as strong as its weakest link. A favorable variation, say a larger horn in the elk, if unaccompanied by corresponding variation in all the thousand parts (in head, neck, trunk, limbs) coördinated with it, would be useless, and even burdensome. In other words, if a single structure (muscle, bone, ligament, etc.) of all those associated with it failed to bear the strain of the larger horn, this variation would not favor survival, but, on the contrary, be a cause of elimination. Therefore, say these thinkers, the evolution of high multicellular animals cannot be attributed to the accumulation, during generations, of inborn variations alone, but must in part be attributed to the accumulation, during generations, of the effects of use and disuse, *i. e.*,

to the accumulation of acquired variations.

But variations acquired as a result of use and disuse are plainly never transmitted. Thus an infant's limb never attains to the adult standard except in response to the same stimulation (exercise) as that which developed the parent's limb. The same is true of all the other structures which in the parent underwent development as a result of use, or subsequent retrogression in the absence of it. These, like the limbs, do not develop or retrogress in the infant except as a result of similar causes. Plainly, then, what is transmitted to the infant is not the modification, but only *the power of acquiring it under similar circumstances*—a power which has undergone such an evolution in high animal organisms that, as I say, in man, for instance, almost all the development changes which occur between infancy and manhood are attributable to it. It follows, therefore, that the exquisite coördination of all the parts of a high animal is not due to the inherited effects of use and disuse, but to this great power of acquiring modifications along certain definite lines; so that if an animal varies in such a way as to have one of its structures (*e. g.*, horn, a structure which is wholly inborn) larger than in the parent, then all the other structures associated with it, owing to the increased strain (*i. e.*, the increased stimulation) put on them, undergo a corresponding modification, and thus preserve the harmony of all the parts of the whole. So also if the horn (for instance) be smaller than in the parent, the lesser strain placed by it on associated structures causes these also to develop less than in the parent, whereby again the harmony of the whole is preserved.

I have dwelt at greater length on this neglected subject of acquired characters (properly so-called) elsewhere,* but I think I have said enough even here to demonstrate its immense importance. The power of acquiring fit modifications in response to appropriate stimulation is that which especially differentiates high animal organisms from low animal organisms.* Without this power and the plasticity which results from it the multitudinous parts of high animals could not well be coordinated, and, therefore, without it their evolution could scarcely have been possible. Indeed, it is not too much to say, so vitally important is this power to the higher animals, that, as regards them, the chief aim (if I may use the expression) of natural selection has been to evolve it. But, since this power of developing in response to the stimulation of use operates mainly along certain definite lines, which are not quite the same in every species, the different species differ as regards size and shape, not only in characters which are inborn, but also in those which are acquired. Thus an ox differs in size and shape from a man not alone in inborn characters, but also in characters which are acquired as a result of exercise and use. The structures of both the ox and man develop in response to appropriate stimulation, but not quite in the same direction, nor in the same proportion, nor to the same degree; hence, to some extent the differences in size and shape betwixt the two animals. Consider, for instance, the hind limbs of the ox and man: in both these grow greatly as a response to the stimulation of exercise, but the lines of growth being somewhat different the limbs do not approximate in shape and size. Presently, when we consider mind, we shall realize even more strikingly the importance of our subject, and perceive how deeply it concerns many fields of thought and investigation which have greatly interested mankind in all ages; but I have still something more to say as regards

* Vide *The Present Evolution of Man*, pp. 108–21.

* The truth of this, as we shall see, is made particularly manifest by the study of mind.

physical characters, though it is not possible in the space allotted me to do full justice to the theme.

G. ARCHDALL REID.

SOUTHSEA, ENGLAND.

THE DESIRABILITY AND THE FEASIBILITY OF THE ACQUISITION OF SOME REAL AND ACCURATE KNOWLEDGE OF THE BRAIN BY PRE-COLLEGIATE SCHOLARS.*

NEVER before has the need of information as to the structure and function of the nervous system been so keenly felt by experts in various branches of knowledge and by practitioners of various specialties.

Never before, likewise, has there been so general and so earnest a desire for such information among the laity. For the first time has it been claimed by a prominent educator that neurology is a prime constituent of a liberal education. Among the branches of knowledge essential to a liberally educated man President Gilman names (*Educational Review*, III., 105–119, February, 1892), "first, the knowledge of his own physical nature, especially of his thinking apparatus, of the brain and the nervous system, by which his intellectual life is carried forward."

Under prevailing conditions, however, any approximation to a real and accurate knowledge of the brain is gained by but few, and at a late educational stage. Hence the public are ignorant or misinformed,* and the time that specialists might devote to research and advanced instruction is consumed in acquiring and im-

* This article is based upon a paper presented at the meeting of the American Society of Naturalists in Boston, December 29, 1896; it is an extension of the views expressed by that Society in 1891, 1892 and 1893 regarding a science requirement for admission to college and the introduction of natural history studies into the lowest grades of schools. It also embodies the substance of published or unpublished remarks upon the subject made by the writer on the following occasions:

1889.—In the article 'Anatomical Terminology,' Reference Handbook of the Medical Sciences (VIII., p. 532, § 82), occurs the following passage: "Aside from prejudice and lack of practical direction as to removing, preserving and examining the organ, there is but one valid reason why every child of ten years should not have an accurate and somewhat extended personal acquaintance with the gross anatomy of the mammalian brain; that obstacle is the enormous and unmanageable accumulation of objectionable names under which the parts are literally buried."

The foregoing paragraph is reproduced in a footnote upon p. 335 of my paper, 'Neural Terms, International and National,' *Jour. Comp. Neurology*, VI., 216–352, December, 1896 (issued February, 1897).

1896, a.—An address before the Home Congress, in Boston, October 13, 1896, was entitled 'Brains for the young: the desirability and the feasibility of the acquisition of some real knowledge of the brain by precollegiate scholars.' Through misapprehension a report of the address was printed in the *Arena* for March, 1897, pp. 575–583. Although unauthorized and containing some errors, it fairly represents what was said.

1896, b.—At the meeting of the New York State Science Teachers' Association in Buffalo, December 31, 1896, in the discussion on Biology in the Schools, the main points of the article above named were briefly stated; they were correctly reported in SCIENCE, April 2, 1897, p. 537.

1897.—A paper on 'The practical study of the brain in a primary school' was read before the University Convocation, June 29, 1897.

*Among the anxious parents and teachers to whom they are addressed how many are able to profit by the information contained in, for example, Donaldson's 'The growth of the brain' and Halleck's 'The education of the central nervous system?' How many persons recognize as erroneous the statements so frequently made as to the supreme absolute or relative size of the human brain? May not high school pupils describe the rivers of Africa and even the 'canals' of Mars and yet be so little familiar with the topography of the cerebrum as to accept without question the alleged representations thereof in most text-books, misrepresentations that might serve equally well for a heap of sausages? A large part of the community is at the mercy of charlatans, and squanders time and money upon that peculiarly American humbug, phrenology as practised. In a recent issue of a popular magazine, whose editor is sincerely interested in education, is an article containing not merely the phrenologic misstatements and vapidities, but a diagram of the 'convolutions of the brain' which has no basis of fact.

parting the neurologic alphabet. Indeed, so numerous are the parts of the central nervous system,* so heterogeneous and unfamiliar are their appellations,† so complex are their connections, so subtle and interdependent are their operations, so multifarious and difficult are histologic and physiologic manipulations, so diverse are the interpretations of nervous phenomena, and so voluminous is the literature of neurology,‡ that by the time existing knowledge is fairly mastered the would-be investigator has too often passed the period of greatest energy, enthusiasm and opportunity.

Were the practical study of the brain commenced in the primary schools two results might be anticipated, viz.:

First, the more general and thorough comprehension of the references to the structure, functions, disorders and injuries of the brain that occur with increasing frequency in lay as well as professional publications.

Secondly, among the many thus early and systematically trained in the fundamentals of neurologic fact, theory, method and literature, such as were fitted by nature and nurture to increase knowledge would be several years in advance of investigators as now prepared.

My general proposition is that *a certain amount of study of the vertebrate brain constitutes an indispensable element of every course at every educational stage; that this study be objective; that dissections and drawings§ be imperatively required; and that the forms and methods employed, and the ideas and generalizations inculcated and elucidated, be adapted to the average mental condition at the several epochs.*

The following remarks and quotations may serve to introduce an outline of neurologic study and to avert some possible objections.

The human brain is commonly the ultimate object of inquiry, but it is so difficult to obtain, preserve, manipulate and comprehend that animal brains are more conveniently employed at first. *Fiat experimentum in corpore vili.*

Descriptions, pictures and models may serve to convey additional information to such as are already fairly well informed; but there should first be laid a concrete foundation composed of direct personal impressions of the object, manual as well as visual.

Other things being equal, the acquisition of advanced knowledge is rapid and perfect in direct ratio with the earliness and thoroughness of appropriate preliminary training.*

The higher a material superstructure, the deeper are laid its foundations. If, therefore, as stated by Minot, the human brain is the most complex organ known, and if the human intellect is destined to be long baffled by the mysteries of its own agent, so much the rather should the fundamental facts and ideas of neurology be firmly fixed in the vacant and receptive depths of the youthful mind.

Because the elaborations of a science tax the mental powers of the philosopher is no reason for postponing its rudiments un-

*Including the meninges and blood-vessels, there are between five and six hundred; see the lists compiled by the committee of the Anatomische Gesellschaft and by the writer; 'Neural Terms,' etc., 1896.

†In 1888 the total in all languages was 10,500; see 'Neural Terms,' etc., pp. 230–231.

‡The card-catalogue prepared in the neurologic laboratory of Cornell University refers mainly to vertebrates and includes between five and six thousand titles.

§In a recent discussion of 'Physiology in the Schools' (University Convocation Report, 1896, p. 74) I have declared my belief that "children should be taught to draw before they write."

*In a very different connection it has been declared by Professor W. W. Goodwin (*The Nation*, October 24, 1895, 'School English') that "whatever study is to be pursued with effect must have its foundations laid before the age of fifteen."

til old age. At one extreme of astronomy are problems of the universe; but at the other is the recognition of the more conspicuous stars.

Mere memorizing becomes more and more irksome and difficult with age, while the youthful mind has been well characterized as 'wax to receive and adamant to retain.' Hence the desirability of the early acquisition of the main facts and terms of neurology.

Children have no prejudices against words of classical origin. *Hippocampus*, *rhinencephalon*, *hypophysis*, *fornix* and *callosum* would be accepted quite as readily as *hippopotamus*, *rhinoceros*, *hypotheneuse*, *appendix* and *chrysanthemum*.

Other things being equal, the readiness with which a new term is assimilated is in direct ratio with the completeness of the impression associated therewith. The pupils who succeed in remembering the names of mountains (*e. g.*, Himalayas) which few can anticipate visiting, and of ancient warriors (*e. g.*, Agamemnon) whose features are unknown to them, will promptly accept and firmly retain the designations of parts of their own bodies, especially when those same parts, obtained from animals, are not merely seen by them, but handled and dissected.

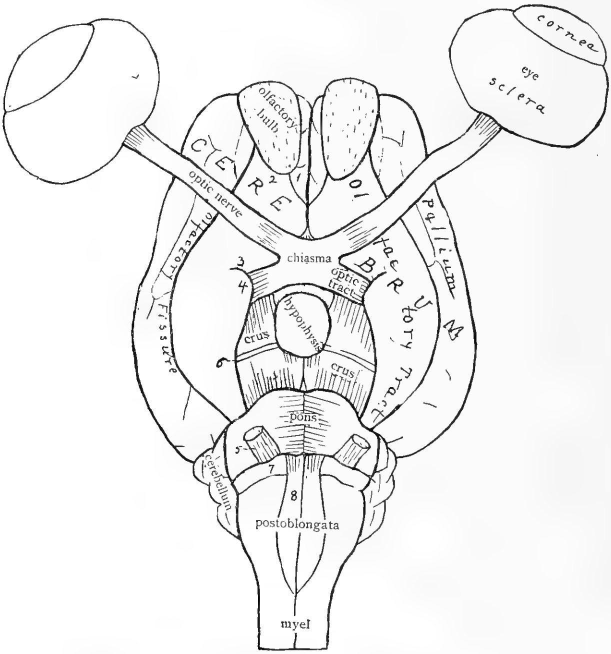

FIG. 1. Base or ventral aspect of the sheep's brain with the eyes attached; slightly enlarged. From the writer's 'Physiology Practicums,' second edition, 1895.

Children are spontaneously interested in natural objects. Like the terror of dogs, the squeamishness that would induce reluctance to handle a 'specimen' is commonly an artificial condition induced by the ignorant or thoughtless interference of parents or teachers. Left to itself the healthy child sucks in knowledge through its finger-tips.

Paradoxical as it may at first appear, notwithstanding the extreme complexity of its ultimate structure, as a gross object the brain is the easiest of all the viscera for the beginner. It is symmetric, and the main divisions are clearly outlined; moreover its colors are attractive, it retains little blood, the natural odor is not offensive, and it has no unpleasant associations.

If it be legitimate to slaughter animals for food, it is even more so to kill them humanely (as with chloroform) in order to gain information. This is particularly true of the superfluous cats and dogs that lead miserable lives in most cities. Children should be taught that the greatest kindness toward such is a speedy and painless death.

The two following sentences, from an artist and a philosopher, respectively, embody profound truths as to physical and metaphysical methods in any branch of study. According to Philip Gilbert Hamerton, "Personal familiarity alone makes knowledge alive." Joseph Henry declares that "In the order of nature, doing comes before thinking, art before science."

Huxley and Wm. North Rice have emphatically condemned the maxim, "A little knowledge is a dangerous thing." Ignorance alone is perilous, and in proportion to its density.

The practical study of the brain in educational institutions below the college may conveniently form three stages, corresponding with the primary school, the grammar and intermediate schools and the high school. At all three stages actual specimens are to be used and drawings are to be made.

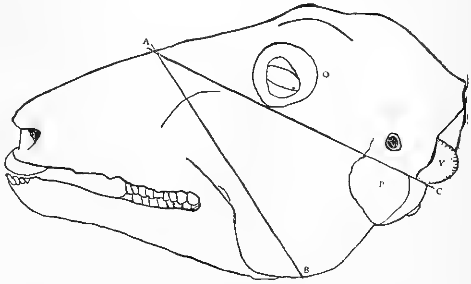

FIG. 2. Head of sheep skinned. Along the line A–B the butcher may cut so as to remove most of the face; the line A–C indicates the plane of section with a saw for removing the cranium.

In the primary stage there is to be mainly *observation* with the unaided eye, and simple manipulation. A sheep's brain* is to be examined by each pupil; but there should be shown also preparations exhibiting the location of the brain in the head, its continuity with the myel (spinal cord), and its connection with the eyes and larger cranial nerves; also preparations, models or charts of corresponding aspects of the human brain. Few terms need be employed, but the parts should become familiar as the features of the face. For further details see the description of an application of the plan in the latter part of this article.

* In most localities where neurology is likely to be considered the heads of sheep may be had in abundance, at a trifling cost, and without involving the killing of the animals for the purpose. In varying degrees the same may be said of calves, pigs and oxen. Sometimes the butchers can be employed to extract the brain after a rough fashion as if for food; but it is removed most safely and easily according to the method devised by P. A. Fish, described by me before the American Society of Naturalists, in 1890, and indicated upon Figures 2 and 3.

In the grammar* school observation is to be extended to *comparison*; with the sheep's brain as a standard the brains of cats and dogs and rabbits are to be examined, drawn and dissected in the same way. All the cranial nerves may be identified. The general nature of cerebral fissures may be considered, and certain special points elaborated, *e. g.*, the distinction between the

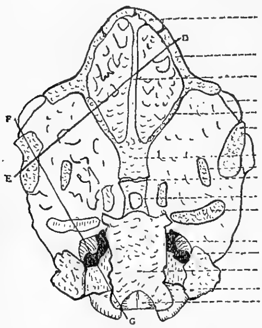

FIG. 3. Ventral aspect of the cranium after removal along the line *A–C*. If the parts outside the line *D–E* and *F–G* are sawn off the brain may be exposed with nippers.

fissures of the cat and of the dog; the difference between the right and the left; the extent of individual variations. Pigs, kittens and puppies† at various ages, before and after birth, may illustrate changes in the form and proportions of parts. A lens may be required for some purposes. The fibrous nature of the white portions may be demonstrated upon hardened specimens.

* In his admirable address, 'Science Teaching in the Public Schools,' (*Amer. Soc. Naturalists*, 1897; *American Naturalist*, September, 1888; also with Appendices, D. C. Heath & Co., 1889), Wm. North Rice assigns the nervous system to the fifth of the nine grades recognized in the primary and grammar schools; but there is also an implication that the study of the brain as an object is to begin in the high school.

† Fetal pigs may usually be obtained at any large slaughter-house.

In the high school, with further observation and comparison should be associated *reflection*. The pupil should be led to recognize the segmental constitution of the brain, and the modifications of the several segments. For this purpose, after a trial of several forms, I believe the brain of the large Green turtle (*Chelone mydas*) of the Atlantic is most available.* The severed heads may be obtained from city hotels, and the brain readily exposed by sawing off the larger part of one side. Afterwards may be studied the brains of other turtles, of salamanders, of lizards and of small mammals, and finally those of frogs and birds. The compound microscope should now be employed for the demonstration of cell-clusters and fiber-tracts in certain regions. In every high school there should be at least one well preserved adult human brain; also that of a monkey. The main resemblances and peculiarities of the former may then be illustrated. Each pupil should have an opportunity of studying the topography of the human cerebrum, and the general arrangement of the fissures should be as familiar as the river systems of his native country. The order of formation of the fissures should be shown upon a series of fetal brains, or models or diagrams thereof.

The foregoing outline is not assumed to be complete or perfect, and the experienced teacher will of course modify the details in accordance with the circumstances.

An opportunity for a partial test of its validity was afforded last spring with a class of forty boys and girls between seven

*Even were the commonly employed brain of the frog not too small, the insignificance of the cerebellum and the secondary fusion of the olfactory bulbs are apt to occasion misconceptions. Indeed, so aberrant is the structure of the frog in most respects that the ease and safety with which it may be obtained, kept alive and experimented upon, constitute a real and considerable bar to the formation and diffusion of sound morphologic ideas.

and eleven years old in the second grade of a primary school. Among the fathers of these children half a dozen are day-laborers and as many more teachers or clergymen, the majority being mechanics or tradesmen.

With the approval of Superintendent H. W. Foster, of the Ithaca Schools, and the cordial cooperation of the teacher, Mrs. H. A. Surface, but with absolutely no advance intimation to the pupils themselves, on the 26th of April there was placed before each of the forty a hardened sheep's brain. During one-third of the half-hour exercise the pupils made drawings of the dorsal aspect of the brain. The rest of the time was spent in discussing the form and naming the main features by the aid of the blackboard. At a second exercise the base was drawn (Fig. 3). At a third each brain had been transected at two levels, *viz.*, between the cerebrum and the cerebellum, and through the frontal part of the cerebrum. After considering the contours and colors of the regions thus exposed, the middle piece was held under water, and air blown into the single orifice in the mesencephal; its escape through the two cerebral orifices demonstrated the continuity of the cavities.

Most of the pupils manifested an eager interest, and only one or two a slight disinclination to handle the specimens.

Twenty names were introduced, nearly in the following order: *cerebrum, cerebellum, olfactory bulb, oblongata, spinal cord,** *arachnoid, pons, chiasma, optic nerve, hypophysis, crus, alba, cinerea, cortex, cavity, endyma, fissure, gyre, pia* and *callosum*. After an interval of nearly two months, at an unannounced examination, most of the pupils were able to recall the main features and their names.

Lest it be hastily inferred that I advocate the introduction of the study of the brain as an isolated branch of biology, let me state, first, that the laws of New York prescribe instruction in physiology for all grades; secondly, that the three lessons above mentioned were merely the last of a series of thirty given by me to the same class, all illustrated by specimens and simple experiments. For the encouragement of others who may desire to further the establishment of objective science teaching in the public schools, it may be added that evidence as to the acceptability of this contribution was received from all parties concerned, *viz.*, the superintendent, the teacher, expert visitors, parents and, by no means least significant, the pupils themselves in the form of spontaneous letters. Two indirect results deserve special mention. The pupils discussed the lessons with their parents (some of whom, by the way, had themselves been my university students); so far from interfering with other work, the interest aroused by the object lessons in physiology was reflected upon totally different branches of study, a point worth considering by those who apprehend that there is no room for science teaching in the public schools.

Appendix: Some educators are concerned as to what shall replace the classics in the curriculums where they are no longer required.* Why not neurology? It is certainly difficult enough, and for most persons —beyond a certain point—it would be quite as attractive and useful. Incidentally, too, there would be learned a by no means insignificant amount of Latin and Greek. This proposition should form the subject of a separate article, but in passing I desire to record publicly the cŏnviction that has been frequently expressed to my colleagues during my twenty-nine years of service, viz., that a certain minimum of both Latin and Greek should constitute a part of the intel-

* Under all the circumstances it seemed best to waive my personal preference for *myel*.

*See, for example, the article, 'After Latin and Greek, what?' in (Boston) *Journal of Education*, XLV., p. 196, March 25, 1897.

lectual equipment of every college graduate; not as entitling him to the name of classical scholar, but as enabling him to comprehend his mother tongue and use it to better advantage, and as facilitating the acquisition of scientific terminology.* That minimum should certainly not be less than what, at my suggestion, has long been required for admission to the two years' course preparatory to the study of medicine at Cornell University, *viz.*, the equivalent of four books of Cæsar's 'Gallic War' and of Goodell's 'The Greek in English.'

BURT G. WILDER.

* Linguistic errors may not vitiate anatomic knowledge, but such inaccuracies as *plexi* as a plural of *plexus*, and *pontic*, *pontine* or *pontal* as the adjective from *pons*, tend to arouse in classical scholars a general distrust of their perpetrators.

THE NATIVE DAHLIAS OF MEXICO.

THE *Dahlia*, botanically speaking, is purely an American genus confined to Mexico. When the Spaniards first visited Mexico they found a people who had advanced considerably out of the state of barbarism. Not only did these people have well-governed towns, but they were agriculturists and horticulturists. They cultivated fruits and vegetables, and in their gardens were many handsome flowers transplanted from the native soil. The Dahlia seems to have been one of these plants. So struck was he by the beauty of this flower that Hernandez, who visited Mexico in 1615, in his History of Mexico, published in 1651, makes mention of two species, one with pale red flowers which grew in the mountains of Quanhuahuac, and was called by the natives *acoctli*. A little over a century later, M. Thierry Menonville, a well-known French botanist of his time, was sent to Mexico by his government to steal the cochineal insect from the Spaniards. While on his dangerous mission Menonville saw the Dahlia on several occasions, and on his return to France, in 1787, published a book of his adventures, in which he spoke of the beauty of the strange flower which he had seen.

About 1788 some seeds of the Dahlia must have been sent to Madrid, for it is recorded that plants flowered for the first time in the botanic gardens of that city in October, 1789. A few of these seeds were secured by Lord Bute and sent to England, where they flowered in 1790. The plants, however, were soon lost, owing to the mistaken idea that they required stove treatment. About this time this species received the name of *Dahlia coccinea*, the generic name being given by Cavanilles, a Spanish priest and one of the most eminent botanists of his day, who was at that time the head of the Royal Gardens at Madrid. The genus was named in 1791 in the Icones Plantarum by Cavanilles in honor of Andreas Dahl, a Swede, a student and disciple of the great botanist Linnæus. Later, Carl Wildenow, objecting to the name *Dahlia*, on account of its similarity to *Dalea*, renamed the plant *Georgina* after Georgi, a Russian scientist and traveller. According to Salisbury, a second species, *Dahlia variabilis*, was introduced into England in 1804 by Lady Holland, who sent the seeds from Madrid. Its behavior under cultivation is described by Salisbury in his paper read before the Horticultural Society in 1808 and printed in the first volume of the Transactions.

The most successful early cultivator of the Dahlia appears to have been Count Lilieur at St. Cloud. He had four distinct varieties to work on in 1808. The experiments of the florists began in 1813, and a writer in a horticultural magazine of 1818 says that with each new year came new varieties until the kinds seemed almost like new creations, so different were they in color and form. Count Lilieur several years before had purples, dark reds, cherry-reds, buffs and

even pale yellow flowers. In 1850 the Dahlia appears to have reached the height of its popularity, after which date it began to decline until the year 1870, when the Dahlia Society founded in that year brought about a revival of interest in the plant. In 1872 additional interest was aroused in the Dahlia by the introduction of *Dahlia Juarezii*, the Cactus Dahlia said to have been obtained from Mexico by a Dutch nurseryman, Donkelaar. The organization of the American Dahlia Society within the last two years has added much to the re-awakened interest in the plant.

As early as 1841 one English dealer had over twelve hundred varieties. This shows the wonderful variability of the plant, which had been in cultivation practically only twenty-seven years. This, however, is not surprising, when we take into consideration the range of variation of the plant in a state of nature. While visiting the Valley of Mexico last summer the writer had the opportunity, as well as the privilege, of botanizing with the veteran botanist and collector, Mr. C. G. Pringle. The slopes of the southern range of mountains known as the Sierra de Ajusco were visited. The Dahlias were found growing in the greatest profusion on the lava beds, known locally as the Pedrigal, literally the Stony Place. Acres and acres of the Pedrigal in the latter part of August are one mass of color of the most varied hues and shades. As the train of the Mexico, Cuernavaca and Pacific Railroad carries you up from Contreras, at the foot of the Sierra de Ajusco, toward the top, where the Valley of Mexico lies spread out before you as a most pleasing panorama, you are carried up through woods that are a wild Dahlia garden—masses and masses of flaming blooms of three species of *Dahlia* in many distinct colors. Here are associated within a small area many beautiful plants with showy flowers, Bouvardias, Senecios, Stevias and the three species of *Dahlia*, viz: *Dahlia coccinea*, *Dahlia variabilis* and *Dahlia Merckii*.

Dahlia coccinea, *Dahlia variabilis* and *Dahlia Merckii* are three of the most common and best known Dahlias which grow in Mexico. Of these *Dahlia coccinea* has the more northerly and by far the most extensive distribution. From the Cordilleras of Chihuahua, within 200 miles of the United States boundary, it ranges southward through the mountains to Jalisco and the Valley of Mexico.* *Dahlia variabilis* is confined to the region around, including the Valley of Mexico. It is a most striking plant, growing from 5 to 6 feet tall, and bearing flowers ranging in color from purple to sulphur-yellow through the following gradations: lavender-purple, heliotrope, heliotrope-yellow (various shades of lighter and lighter hue approaching yellow) sulphur-yellow. The heads of which the ray florets are colored heliotrope-yellow are in reality of an heliotrope color, the bases of the ligulate corolla being of a yellow color shading off into heliotrope. They are broad (1 inch), long (2 inches) and ovate spatulate.

Likewise, *Dahlia coccinea* shows a remarkable variation in color from cardinal of several shades through scarlet, scarlet-orange, mandarin, orange, lemon-yellow, yellow.† The so-called scarlet-orange rays are scarlet with lines of yellow running through, so that the strap-shaped corolla has a somewhat banded appearance. The ligulate corolla is about an inch long and half an inch broad. The entire head varies in size from two inches in the cardinal ones to three inches in the scarlet-orange ones.

Dahlia Merckii runs from purple to pure white through the gradual fading-out of the

*1891, Pringle, *Garden and Forest*, IV., 40.

† These colors have been compared with the colored silk samples issued by Belding & Co. and the Maryland Silk Company, Hagerstown, Md.

purple color. One most commonly sees in a state of nature the white heads which are tinted with lavender or pale purple at the base of the ray floret. The heads in each case are nearly uniform in size, being about an inch and three-fourths across.

There are several other species worthy of mention. *Dahlia imperialis*, *D. scapigera*, *D. dissecta* and *D. pubescens*. *Dahlia dissecta* was discovered by Mr. C. G. Pringle growing on limestone ledges fifty miles east of San Luis Potosi. "It is a very unique species, being scarcely more than two feet high and of bushy habit from an almost woody base." The flower heads are two or three inches broad, with about eight mauve colored rays. *Dahlia pubescens* was found by the same botanist on calcareous bluffs of prairies bordering the valleys of small streams in the State of Mexico and to the north of Toluca. It is a small plant, one and a-half to two feet high, with heads two to three inches broad, with a yellow disc surrounded by eight rays which are purple, with lines of deeper color which changes with age to light purple or dull rose.

The tubers of these plants, particularly those growing on the lava beds along the southern mountainous rim of the Valley of Mexico, are hard to obtain, because of the depth to which they sink in the lava pockets. All of the species store up in their tubers a substance called inulin, chemically allied to starch. The substance is in solution in the cell, much as sugar is, but crystallizes out in needle-shaped crystals upon the addition of alcohol. This substance is stored up as a reserve food to meet the demands of the plant during the active growing season, and the tubers with this stored substance perpetuate the species during the long droughts which are frequent in Mexico.

The dry season in the region of the Valley of Mexico lasts from about the first of October until about the first of June, when there are signs of the returning rainy season. During the drought the tubers of the Dahlias lie dormant until the first rain moistens the soil, when they spring up in great numbers everywhere on the lava beds. The plants grow vegetatively until the end of August, when they flower in the greatest profusion. The rainy season is characterized in the Valley of Mexico by afternoon thunder showers. The morning will be cool, and the air bracing, until evening, when the sky becomes overcast and the rain comes down sometimes in torrents.

A consideration of these meteorological conditions ought to influence the cultivation of the Dahlia, which has not been entirely understood. It will repay some energetic nurseryman to obtain fresh tubers directly from the mountains of Mexico by a personal visit to the native home of the plant. It will repay him to collect tubers of every plant with a different shade of color. As already intimated, the plants in a state of nature are extremely variable. This variation in nature, as compared with the variation produced by cultivation, is just as striking, and shows us that many of the species are in an extremely unstable state of equilibrium as regards their plasticity. This great plasticity in a state of nature explains how so many new colors and forms originated, almost as if by magic, when the Dahlia was first introduced into cultivation. The inherent possibilities of color and form were represented in the protoplasm, and only needed the stimulus of a varied culture to bring out these latent acquired characteristics.

CURRENT NOTES ON ANTHROPOLOGY.

INSCRIPTION OF THE CROSS AT PALENQUE.

THIS most famous of all the Mayan inscriptions has been subjected to a searching analysis by Dr. Förstemann (in *Globus*, Vol.

72, No. 3). He reads it in the direction advocated by Rau, beginning at the left upper corner, and confirms Rau's opinion that it is a chronological record. The very large glyph which in this plan comes first he states is a compound of the three glyphs used for the highest customary time-periods of the Mayas, — 360, 7,200 and 144,000 days, and is to be understood as signifying 'time-counter,' or 'historical table.'

The inscription itself is made up of a series of glyphs representing dates; between these is another series representing spaces of time, and a third class of unknown meaning, perhaps historic facts. If the latter, the glyphs would read like the following:

"March 4, 1893; Cleveland, President; 4 years; March 4, 1897."

Or it may be that not historic data, but religious notions are intended, such as the supposed control of a certain period of time by a certain divinity, etc. At any rate, this scheme of the inscription, whatever its application, seems to be well established by this learned and thoughtful article by the most erudite student of the subject living.

THE ETHNOLOGY OF KISSING.

THE kiss was unknown, I think, among the aboriginal tribes of America and of Central Africa. From the most ancient times, however, it has been familiar to the Asiatic and European races. The Latins divided it into three forms—the *osculum*, the *basium* and the *suavium*; the first being the kiss of friendship and respect, the second of ceremony and the third of love. The Semites always knew the kiss, and Job speaks of it as part of the sacred rites, as it is to-day in the Roman Church.

The Mongolian kiss, however, is not the same as that which prevails with us. In it the lips do not touch the surface of the person kissed. The nose is brought into light contact with the cheek, forehead or hand; the breath is drawn slowly through the nostrils, and the act ends with a slight smack of the lips. The Chinese consider our mode of kissing full of coarse suggestiveness, and our writers regard their method with equal disdain.

Darwin and other naturalists have attempted to trace back the kiss to the act of the lower animals who seize their prey with their teeth, etc. An interesting recent study of the subject is by M. Paul d'Enjoy, in the *Bulletin* of the Paris Anthropological Society, Vol. VIII., No, 2.

THE ABORIGINES OF INDIA.

Two articles on the Dravidian stock of Hindostan have recently appeared. One is by Professor Oppert, in Nos. 4 and 5 of *Globus* (Bd. 72); the other by Dr. Zaborowski in the *Bulletin* of the Anthropological Society of Paris (1897, fasc. 2).

Professor Oppert refers to the Aryan invasion of India, and the profound differences between the two stocks which have been maintained by the caste system until the present day. He points out in detail the sharp contrasts in the morphology of the Dravidian and Ayran linguistic stocks, describing the former as concrete, the latter as abstract in its conceptions. Without directly connecting the Dravidian with the Ural-Altaic group, he draws attention to certain similarities between them.

Dr. Zaborowski reviews the recent ethnographical literature of the subject, and argues that the Dravidians of southern India descend from the same family as the Mois of Cochin China and the Malayan tribes of the island world. He supports this from somatic traits, coincidences of customs and religions, and partially from linguistic research. While his article does not carry conviction, it is a result of a careful study of the question.

SCIENTIFIC NOTES AND NEWS.

THE ROYAL SOCIETY.

THE ROYAL SOCIETY held its anniversary meeting at the Burlington House on the afternoon of November 30th and its anniversary dinner on the evening of the same day. The medals were presented in accordance with the announcement already made, and the officers were re-elected, with the exception of some members of the Council. The officers elected are as follows: President, Lord Lister; Treasurer, Sir John Evans; Secretaries, Professor Michael Foster, Professor Arthur William Rücker; Foreign Secretary, Sir Edward Frankland; other members of the Council, Professor William Grylls Adams, Professor Thomas Clifford Allbutt, Sir Robert Stawell Ball, Rev. Thomas George Bonney, Professor John Cleland, Professor Robert Bellamy Clifton, Professor James Alfred Ewing, Alfred Bray Kempe, John Newport Langley, Joseph Larmor, Professor Nevil Story Maskelyne, Professor Raphael Meldola, Professor Edward Bagnall Poulton, William James Russell, Dukinfield Henry Scott, Professor Walter Frank Raphael Weldon.

Lord Lister delivered the anniversary address, beginning by enumerating the fellows and foreign members who had died during the year, and paying a tribute to those whose scientific services had been the most noteworthy, including Sylvester, Sir Augustus Wollaston Franks, the Rev. Dr. Houghton, Edward Ballard, James Heywood, Weierstrass, DesCloizeaux, Julius von Sachs and du Bois-Reymond.

Lord Lister then proceeded to report on the activities of the Royal Society during the year, including the address of congratulation presented to the Queen, the deputation of the Society to urge upon the government the establishment of a National Physical Laboratory, and its relations with the India office in regard to the treatment of the plague. Lord Lister further referred to Dr. Copeland's researches on variola and vaccinia and to the contributions collected by the Society for the National Pasteur Memorial. At the anniversary dinner toasts were proposed or responded to by the President, Sir John Evans, the Duke of Devonshire, the American Ambassador, Professor Forsyth, Lord Kelvin and Professor Campbell.

THE NEW YORK STATE SCIENCE TEACHERS' ASSOCIATION.

THIS Association will, as we have already announced, hold its second annual meeting at Ithaca on December 30th and 31st, following the sessions of the American Society of Naturalists and the affiliated societies. The objects of such an Association should commend themselves to all men of science, and it is hoped that as many as possible attending the other meetings will remain at Ithaca over Thursday and Friday, and that all resident in New York State will join the Association. The program arranged for the meeting is as follows:

Thursday afternoon at 3 p. m., address of welcome by President J. G. Schurman; paper by Miss Mary E. Dann, of the Girls' High School, Brooklyn, on 'Physical Laboratory Work in Secondary Schools.' Discussion opened by Professor John F. Woodhull, Teachers' College, New York; followed by Professor D. L. Bardwell, Cortland Normal School, and Professor Irving P. Bishop, of Buffalo Normal School.

At the evening session, in the Physical Lecture Room, an address will be given by the President of the Association, Professor Nichols, on 'The Use of the Lantern in Science Teaching' (illustrated by numerous experiments). After the evening session there will be an informal reception at the house of the President.

On Friday morning the report of the committee of nine will be presented on the three following subjects: (1) The recognition of science as a requirement for entrance to Colleges. (2) Science courses for secondary schools. (3) Nature study in elementary schools. A paper by Professor L. M. Underwood, of Columbia University, on 'The Teaching of Botany in Secondary Schools,' will be followed by a discussion by Miss Sarah V. Chollar, of Potsdam Normal School, and Professor W. H. Lennon, of Brockport Normal School.

In the afternoon there will be round tables for the discussion of science teaching, as follows: I. 'Union Schools and Academies,' led by Principal Thomas B. Lovell, of Niagara Falls High School. II. 'Normal Schools,' led by Professor Howard Lyon, of Oneonta Normal School. III. 'Colleges,' led by Professor B.

G. Wilder, of Cornell University. The final paper will be on 'Out-door Science Work in Secondary Schools,' by Principal Frederick A. Vogt, of Buffalo Central High School. Discussion opened by Professor A. D. Morrill, of Hamilton College, Clinton; followed by Professor Chas. B. Scott, of Oswego Normal School, and Professor R. A. Surface, of Cornell University.

A NATIONAL DEPARTMENT OF HEALTH.

THE New York Board of Trade and Transportation has addressed a circular letter on public health and quarantine to the Governors of States, to the Mayors of all important cities, seaboard and interior, and to all State and municipal health authorities, physicians, and known experts on the subject, asking for opinions as to the desirability of creating a national department of health, and requesting suggestions as to the best method of protecting the public health, especially as the same affects interstate commerce, on the following lines:

(1) Quarantine status and administration in foreign countries as furnishing precedents for the United States. A, border; B, internal.

(2) The present status of quarantine in the United States. A, border defence; B, interstate; C, state and local.

(3) The existing system of quarantine administration in the United States. A, cost; B, injury to and restrictions imposed on commerce and travel; C, security afforded.

(4) Legislation needed for lessening injury to and restrictions on commerce and travel, and to afford greater security to the country. A, increase power of Marine Hospital Service and how; or, B, create a national department of health; or, C, create a national department of commerce, with a bureau of health; or, D, other suggestions.

(5) The power of Congress under the Constitution to regulate matters affecting the health of the people. A, national; B, interstate; C, State and local.

THE PROTECTION OF THE SEA OTTER.

THE Treasury Department has recently issued an important and interesting 'Report on the Sea Otter,' by Capt. C. L. Hooper, of the revenue marine, giving an account of its range, habits, method of capture and decrease under American rule almost to the point of extermination. From 1873 to 1883 the annual catch increased from 2,265 to 4,152, and then, as the inevitable result of overhunting, rapidly declined, the catch for 1896 being only 724. So sharp has been the pursuit of this valuable animal that it has changed its habits, no longer coming on shore to feed, rest, or bring forth its young. As about 1,200 natives of the Aleutian Islands are almost wholly dependent on the sea otter for the necessaries of life, it is highly important to make some effort to preserve it, and to do so promptly. With this end in view, a set of regulations for 1898 are appended, intended to preserve the remaining sea otters for the use of the Aleut hunters and their families, in accordance with the spirit of article 1,956, Revised Statutes. The Report is accompanied by a map showing the sea otter grounds, which lie mainly to the southwest of Kadiak and in waters considered to be within the jurisdiction of the United States. If so, the proposed regulations, properly enforced, will furnish ample protection; if not, an international agreement would be necessary and a limit of fifteen miles from shore. The remaining otter would then be protected, and hunting from schooners being prohibited, the natives would be compelled to hunt from the shore, and the otter would have some chance of increasing.

GENERAL.

WE record with regret the death of the Hon. Gardiner Greene Hubbard, at his residence near Washington, on December 11th, in his 76th year. He was President of the National Geographic Society, whose great success was almost entirely due to his efforts, and was prominent in all movements for the advancement of science at Washington. The first series of this JOURNAL was greatly indebted to him for his counsel and financial support, it having been established by him and Professor A. Graham Bell.

A BUST of Pasteur was unveiled on November 28th at Melun as a memorial of his anti-anthrax vaccine. On the same day a memorial to him was also unveiled at Boulogne, an address being made by M. Gaston, Paris.

AT the anniversary meeting of the Royal Society Lord Lister announced that Sir William Mackinnon, late Director-General of the Med-

ical Department of the Army, had, by will and codicils dated 1896 and 1897, after making certain specific legacies, including one of £2,000 to the University of Glasgow, bequeathed the whole residue of his property to the Royal Society, subject to certain life annuities. The proceeds of the fund were to be applied by the Royal Society for the foundation of such prizes and scholarships for the special purpose of furthering natural and physical science, including geology and astronomy, and for furthering original research and investigation in pathology, as the Society might think best and most conducive to the promotion of those sciences and of original discoveries therein; such prizes and scholarships to be called after the name of the testator.

THE Berlin Academy of Sciences has made a further appropriation of 3,000 M. for the History of the Academy now being prepared by Professor A. Harnack.

E. CZABAN, a Warsaw merchant, has bequeathed 50,000 roubles (some $35,000) to the Warsaw Academy of Sciences and also 30,000 roubles to both the University of Cracow and the University of Lemburg.

THE Indiana Academy of Science will hold its annual meeting at Indianapolis on December 28th, 29th and 30th, under the presidency of Professor Thomas Grey, Terre Haute, Ind.

THE Lick Observatory eclipse expedition, from San Francisco, has arrived at Bombay and will proceed inland to select an observing station.

IT is reported that an endeavor will be made to found an astronomical observatory at Glasgow.

THE Marine Biological Station of the University of Tokyo, at Mazaki, will be removed during the present year to a new site about two miles north of the present location. A proposed railway will bring the station within two or three hours of Tokyo.

A MARBLE bust in memory of the geologist A. Stelzner has been unveiled in the School of Mines at Freiburg.

IT is proposed to commemorate the late Mr. J. Greig Smith, M.A., M.B., C.M., Aberdeen, professor of surgery at University College, Bristol, by erecting within the precincts of the University of Aberdeen a memorial tablet.

DR. CAMPBELL MORFIT, the chemist, died on December 8th in London. He was born in Herculaneum, Mo., November 19, 1820. He was formerly professor of applied chemistry in the University of Maryland. In 1858 he removed to New York, where he followed his profession until 1861, when he went to London.

THE death is announced of Mr. Ernest Giles, the Australian explorer, who between 1874 and 1875 twice traversed the West Australian desert from Adelaide to Perth. The Royal Geographical Society awarded him its founder's medal for his journey.

BILLS have been introduced in both branches of Congress prohibiting pelagic sealing by citizens of the United States.

SECRETARY LONG has issued an order transferring the Naval Hydrographic Office from the control of the Navigation Bureau to the Bureau of Equipment. The latter bureau now has charge of the Naval Observatory and similar branches of the service.

ONE hundred employees of the Gypsy Moth Commission have been discharged, the appropriation made by the Legislature being nearly exhausted.

LIEUTENANT R. E. PEARY, having again complained in London of Captain Sverdrup's unfairness in going to Smith Sound next summer, Captain Sverdrup explains that he wrote to Mr. Peary some time ago saying that he did not aim to reach the pole, but only intended to explore Greenland and to make a study of the ice.

THE Zurich correspondent of the London *Times* writes that at Windisch the old Roman colony of Vindonissa, in the Canton of Argovie, excavations recently carried out under the auspices of the Swiss Archæological Society have yielded important results. Large Roman villas and an amphitheatre have been disinterred and, besides a large quantity of coins, pottery, bronze and ironware, some large silver vessels have been discovered, which are said only to have their equals in the famous treasure-trove

of Hildesheim, in Germany, brought to light in 1868.

THE daily papers report that uranium has been discovered near Black Hawk, Col. The mineral is worth $1,500 per ton, and the agents of a French syndicate have announced that they will buy all that can be produced, as it is much desired by the French government for hardening and solidifying gun metal and armor plate.

THE American Forestry Association held its 16th annual meeting at Washington on December 8th. General Francis H. Appleton, of Boston, presided and made an address. The chairman of the Executive Committee, Dr. E. B. Fernow, presented a detailed report, reviewing especially the legislation of the past session of Congress. The Association proposes to establish a monthly journal, *The Forester*, devoted to the interests which the Association is doing so much to forward. The summer meeting of the Association will probably be held at Boston, in conjunction with the American Association for the Advancement of Science.

THE British Institution of Electrical Engineers, which now numbers 3,000 members, held its annual dinner on November 24th. Addresses were made by Lord Kelvin and others.

IT is expected that the life of Pasteur by his son-in-law, M. Vallery Radot, will soon be ready for publication.

M. ALCAN announces, in the next volume of the French edition of the 'International Scientific Series,' a work on the physiology of hearing by Dr. Gelle.

THE *Open Court* continues in the December number the series of portraits of mathematicians, with the reproduction of an old steel engraving of Lagrange, of whom Dr. T. J. McCormack gives a biographical sketch.

AT the anniversary dinner of the Royal Society on November 30th Lord Kelvin referred to the presence of representatives of many foreign powers and of the Ambassador of the United States, who, he said, 'could not be regarded as a representative of a foreign nation.' In his address at the dinner Lord Lister remarked: "That among the great number of eminent Americans who attended the Canadian meetings of the British Association and the Medical Congress there was never a jarring note; there was never anything but cordiality and kindly feeling towards the old country."

MAJOR M. P. HANDY, special commissioner to gather information regarding the Paris Exposition of 1890, recommended the appropriation of $915,000 towards the expenses of preparing a proper representation for the United States. The sum includes $1,500 per year for three years for each of nine scientific experts. In his report Major Handy says: "The industrial progress of the United States, and the evolution of its material resources during the hundred years which the Exposition is to crown, has been unequalled by that of any other nation. It is not too much to say that the United States now stands the greatest nation of the world in all the great lines of industry. According to the figures given by the eminent statistician Mulhall in his 'Industries and Wealth of Nations,' the United States leads in agriculture, with products greater than Russia and the United Kingdom combined; in the manufactures with a product of greater value than the aggregate output of the factories of the United Kingdom, France, Austria-Hungary and Belgium combined; in machinery with a greater steam power than the United Kingdom, Austria-Hungary and Italy combined; in mining with a product greater than the United Kingdom and France combined, or nearly one-third of that of the entire world; in railway transportation with a mileage 40 per cent. greater than that of all Europe; in forestry with products greater than that of all Europe, and nearly one-half of the total products of the world; in fisheries with a greater product than the United Kingdom, Russia and Germany combined."

THE English papers report that the Guilford Natural History Society have been considering the question of the preservation of Wolmer Forest, which is only fifteen miles from that town, and have decided to present a petition to the Commissioners of Woods and Forests, praying that Wolmer Forest may be reserved as a sanctuary for wild birds, in which they, their nests and eggs may remain unmolested

throughout the year; that it may not be let at any time for game preserving, or for any purpose inimical to bird life; and that it may remain in perpetuity as a national memorial to the greatest outdoor naturalist England has produced—Gilbert White, of Selborne. Such a recognition, the Society urge, would show that the admiration of Gilbert White in the nineteenth century was so practical as to be of value to the naturalist and the English-speaking race for all succeeding time. The Society have no wish to attempt to interfere with the use of the Forest by the War Office for the purposes of military manœuvres.

UNIVERSITY AND EDUCATIONAL NEWS.

BILLS have been again introduced into both Houses of Congress to establish the University of the United States. Such a bill was introduced by Senator Edmunds in 1890 and referred to a select committee, which reported unanimously in its favor. The standing committee since appointed has also reported unanimously in its favor and it is said that the bill will probably be passed during the present session.

NEGOTIATIONS are said to be under way looking towards the affiliation of the University of Chicago and the Rush Medical College.

EVELYN COLLEGE, Princeton, has been closed, owing to the fact, as stated by the principal, that Princeton University refuses to recognize any work for the education of women.

MR. FRANZ KEMPE, of Stockholm, has given the University of Upsala the sum of about $45,000 for the establishment of an associate professorship of physiological botany under the condition that Dr. Lundström be the first incumbent.

BY the will of the late F. Ulrich the German University of Prague receives 100,000Fl. for the distribution of scholarships.

A PROPOSITION has been introduced into the French Chamber and referred to the Education Commission creating a chair of colonial science in the University of Paris.

PROFESSOR WALDEMAR LINDGREN, of the U. S. Geological Survey, has been appointed to the chair of metallurgy and mining engineering in Stanford University.

MR. EDGAR R. CUMINGS, of Cornell University, who graduated from Union College last June with honors in geology, has been appointed instructor in geology in the University of Indiana.

DR. W. OPHÜLS, assistant in the University of Göttingen, has been called to the chair of pathological anatomy in the University of Missouri.

DR. S. FUCHS has been promoted to an associate professorship of physiology at the University at Jena.

THE regents of the University of the State of New York have just published as bulletin 38 a compilation of all the laws, ordinances and by-laws pertaining to higher education in this State. It includes not only the University law, but also the educational articles from the Constitution and the various statutes governing professional education and license to practice, and other allied matters. Its practical utility is greatly increased by many annotations and cross references and by a very full index, so that every lawyer or school officer will find it indispensable when considering any of the large class of questions covered. It is being sent to every institution in the University free, but lawyers or others interested may obtain copies from the regent's office, post free, at the nominal price of 15 cents for the 108 pages.

THE report of the Sites Syndicate of Cambridge University was approved on November 25th. By it provision was made for sites for the erection of a law school, for new buildings for the department of botany, for a museum of general and local archæology and of ethnology, to be erected on ground purchased from Downing College. The mathematical professors are to be provided for by buildings to be erected on the site purchased from Messrs. Murtlock & Co., while the rooms now occupied by them are to be assigned, together with the bird room, when vacated, to the department of morphology. The rooms between the bird room and the department of physiology are to be assigned to the departments of physiology and morphology. The present Geological Museum in Cockerell's buildings and the rooms in Scott's buildings occupied by the University for business pur-

poses are to be appropriated to the University library as soon as they can be vacated. The site now occupied by the old Anatomical School, part of the pathological department and a portion of the unoccupied part in Downing street is to be reserved for the erection of new buildings for the medical, surgical and pathological departments.

DISCUSSION AND CORRESPONDENCE.

THE UNITED STATES FISH COMMISSION.

THE recent editorial of SCIENCE on the subject of the United States Fish Commission is unfortunately misleading in some of its statements, and, in justice not only to the Commissioner but to the entire personnel of the Commission, these should be corrected.

While the amount of scientific work accomplished under the direction of the Commission may not be as great as men of science might wish, it must be remembered that, after all, the primary object of the Commission is to preserve and increase the fisheries, and, so far as this can be accomplished by artificial propagation, this has been done. Moreover, it should be borne in mind that, aside from salaries, the sum to be expended in any one branch is determined by the appropriation committee, and the appropriation for 1898 contained $132,000 for the propagation of food fishes and but $10,500 for scientific research.

A comparison of the annual reports for a few years back will show that it is hardly just to say that 'the efficiency of the hatcheries and of methods of distribution cannot be advanced or even maintained.' In regard to the oyster the work of Dr. J. A. Ryder and others under the Fish Commission is well known, and it may be said that the investigations of the past two years compare favorably with those of previous years, and that important reports on the subject have been published.

In regard to the lobster it is hardly correct to say that 'we are not told how many eggs are killed at the hatcheries,' when the report of the Commissioner definitely says that '128,000,000 eggs were secured, producing 115,000,000 fry.' The rest of the matter is unjust because, as in the case of shad, the eggs were *all* obtained from animals taken for market, and had they not been purchased by the Fish Commission the eggs would have been a total loss to mankind, and the adult lobster would have been killed instead of being returned to the water. While the sale of 'berried lobsters' is prohibited by law, very little regard is paid to the statute, as it is an easy matter to scrape off the eggs and sell the females without running the least risk. Instead of the work being analogous to 'taking all the babies born in New York City and depositing them in a baby farm,' it is like rescuing them from 'baby farms' and worse, and transferring them to a municipal orphan asylum.

That the Commissioner of Fisheries should have a practical and scientific knowledge of fishes is undeniable, but meanwhile let us at least be just to the present one. F. A. L.

[CERTAINLY the Fish Commission should be given its due. It is, as we stated in the article referred to, doing a useful work in the distribution of fry, but does F. A. L. really believe that this can be done in the most satisfactory manner under the direction of one ignorant of the life-history, habits and natural environment of fishes? What does F. A. L. regard as the probable outcome, should all the scientific departments, bureaus and surveys at Washington be placed under the charge of professional politicians and their relatives and supporters? Dishonesty would soon follow inefficiency, and the present condition of the Fish Commission, bad as it is, would be looked back to as relatively ideal. In mentioning Ryder our correspondent calls attention to work of the kind that the Commission is no longer able to carry out. If we differ from F. A. L. as to the efficiency with which the lobster is propagated, is the present Commissioner competent to decide who is right? We have no wish to suppress discussion in this JOURNAL, but it is unfortunate if men of science cannot unite in maintaining principles on which depend the scientific and economic work under the government.—ED. SCIENCE.]

A NATIONAL DEPARTMENT OF HEALTH.

TO THE EDITOR OF SCIENCE—In the excellent article on 'The Progress and Achievements of Hygiene,' in your issue for November 26th, there is an error of omission which, whether intentional or not, should not be allowed to pass uncorrected in a journal so prominent as SCIENCE.'

On page 796 the writer says: "Since Congress has failed to act upon the President's repeated recommendation and the petitions of numerous medical societies for the creation of a National Health establishment, there is no good reason why the scope of duties and powers exercised by the Marine Hospital Service should not be enlarged;" making no allusion, whatever, to the comprehensive bill recently drawn up by the American Medical Association, to be urged before the present session of Congress.

The bill, as formulated, provides for an independent department, of which the Marine Hospital Service shall constitute, as it should, a subordinate bureau.

The conservation of the public health, considered even from a purely economical standpoint, is of national importance and should be relegated to no subordinate bureau with or without 'an advisory board.' To do so would be to postpone, perhaps for decades, the imperative and rational step which should be taken now.

The head of the new department ought to be made a cabinet adviser, but perhaps this may not be at present. If necessary, the Constitution can and will in time be altered to give it additional powers consonant with the requirements of modern sanitary science. To quote Dr. Girdner in the *North American Review* for the present month, what is needed is: "A unifying and supervising force in the national government which will direct, harmonize and render efficient the agencies of the various States."

C. H. PRESTON.

DAVENPORT, December 7, 1897.

SCIENTIFIC LITERATURE.

Habit and Instinct. By C. LLOYD MORGAN. London, Edward Arnold. 1896. 8vo. Pp. 352.

This is a work on comparative psychology largely based on observations of bird life, and containing appropriate speculations concerning the origin and development of certain mental phenomena. The press work is excellent, the one illustration fair and the binding poor.

In the preface Professor Morgan makes a gracious allusion to those whom he met during his lecture tour, and he shows throughout the entire book an appreciation of, and a remarkable familiarity with, the work of American biologists. This may be due to the fact that 'Habit and Instinct' is the embodiment, in book form, of a series of lectures delivered in various university centers of the United States; but one experiences an exhilarating sensation of novelty in reading a book on modern biological problems which is neither supported by the legs of Lord Morton's mare nor infested with bob-tailed mice and epileptic guinea pigs.

First, defining his use of such terms as habit, instinct, reflex action, connate and deferred activities, automatism, etc., he divides the animal activities into those which are inherited and those which are acquired. From the biological point of view, habits are acquired activities of the individual, while instincts are congenital activities not characteristic of the individual alone, but of all the members of the group to which the individual belongs.

The first third of the book is largely descriptive of the habits of young birds and mammals, the birds in particular being selected from representative groups. The anecdotes are told in a most entertaining manner, but one fears that, as the embryologist drew many false conclusions from data supplied by the highly specialized meroblastic egg of the hen, so the comparative psychologist may be deceived by the data furnished by the highly specialized mental equipment of the bird. Though the observations would doubtless prove less entertaining, it is in the lower rather than in the higher vertebrates that one would search for the more simple and less involved mental phenomena. The anecdotes are generally pertinent, but a half page of speculation as to how a pig would jump out of a chair is neither instructive nor conclusive.

Having arranged his data, Professor Morgan really begins his work in the sixth chapter,

where he maintains that the first instinctive act (for example, the first peck of a newly hatched chick), the more automatic result of an inherited motor coordination, supplies to consciousness its first experience-data. "This is due to complex groups of incoming currents, from the parts concerned in the response, along afferent nerves to the sensorium." On this first occasion the consciousness arises wholly by back-stroke. "On subsequent occasions, under associative suggestion, revivals in consciousness of previous experience-data modify the whole process and introduce the effective guidance of consciousness," * * and * * "This profiting by individual experience is of the very essence of intelligence."

If the revivals in consciousness are pleasurable the activity is augmented; if unpleasant or painful it is inhibited. The repetition of the act becomes, then, a matter of conscious choice, and through reiteration the action becomes ingrained and habitual. "On this conscious selection and choice depends * * * the development of those habits which are acquired as opposed to those which are congenital; and * * * the whole mental as contrasted with merely biological evolution."

In treating of imitation, while it is admitted that there may be imitative organic response, independent of experience, the incentive to intelligent imitation is the pleasurable sensation which the imitator receives when his acts resemble the acts of others. The tendency to imitate is thus based on an innate proclivity, and is the means of securing to the organism a congeries of acquisitions which, perfected through repetition, may finally become habitual. In the opinion of Professor Morgan, already expressed in an earlier work, the value to the organism of the imitative tendency is vital. On its presence the questions of survival or destruction frequently depend, for the imitation of the quick-witted and alert is often the salvation of the more stupid. In gregarious animals, through 'tradition,' acquisitions are handed down from generation to generation without the aid of hereditary transmission.

The motif in the chapter on 'Emotions' is the elaboration of the theory of James, namely, that the emotion originates, is primarily generated, by a back-stroke from the motor organs and viscera, and thus 'all the data of sense experience are of peripheral origin.' Though Morgan's observations appear to be in accord with this view, the reader may not feel thoroughly convinced that the emotions are universally the conscious effect of the back-stroke from the visceral actions.

In the succeeding chapter the author shows that though an emotion is private to, and exclusively for, the individual receiving the back-stroke, the subsequent 'expression' may be, and often is, an indication to others of the particular emotional state. "So long as the expression indicates an emotional condition which shows that the animal means business, that is enough from the biological point of view." He thus incidentally reconciles Wallace's theory of exuberant vitality with commonplace sexual selection. Exuberance of vitality may be expressed, on the one hand, by emotion (song, etc.), and, on the other, by peculiarities of structure (plumes, etc.). Both may be of varying potency in arousing the sexual instinct of the opposite sex, and thus of varying selective value. "Stripped of all of its unnecessary æsthetic surplusage, the hypothesis of sexual selection suggests that the accepted mate is the one that most strongly evokes the pairing instinct."

The view is advanced that the song of birds, unlike their calls and alarm notes, may be 'traditional' and due to imitation; and the question of the instinctive nature of the peculiar antics and aërial evolutions of certain birds, before and during the breeding season, is raised. But 'in all these matters further and fuller evidence from direct observation is to be desired.'

The sordid questions of domestic economy, nest-building, incubation, the care of young, etc., are now discussed and the questions raised: Are these phenomena instinctive or are they intelligent? Are they congenital or are they the result of individual experience? If instinctive, are they attributable to natural selection alone, or to the inheritance of acquired habit? So far as certain of the phenomena are concerned, the author favors a possible cooperation of natural and intelligent selection, though he concludes that as matters stand 'the ques-

tion must be left open.' Questions arising in connection with the migratory habit are left in a similar way.

Professor Morgan now lays special stress upon consciousness as a cooperating factor in organic development. In the earlier chapters it was assumed, for the sake of simplicity, that mental evolution might be concomitant with, rather than a factor of, organic evolution. His presentation of the difference between organic evolution as a result of the elimination of the unfit, and of organic evolution as a result of conscious choice, through the elevation of the fit, is extremely ingenious, and the part that the latter may play in the struggle for existence is clearly shown. "In so far as conscious adjustment aids in the struggle for existence, in so far through it the animal is better able to escape danger, to secure a more favorable habitat, to gain a mate and beget progeny; the animal possessed of intelligence will escape elimination, transmit his power of conscious adjustment, and contribute to the propagation of his race. Without fully subscribing to the doctrine of the all-sufficiency of natural selection, we may yet say that natural selection will exercise a determining influence in deciding the course which conscious adjustment must take."

The question of the inheritance of acquired habits is many times raised, but receives no partisan treatment in the first three hundred pages. In the latter part of the book the author instinctively holds to his earlier belief, while admitting, as a result of his experience, certain intelligent modifications of his views. We quote from page 305:

"If pressed to summarize my own opinion on this question, I should say: First, that there is but little satisfactory and convincing evidence in favor of transmission, but that variation does seem in some cases to have followed the lines of adaptive modification, so as to suggest some sort of connection between them; secondly, that there are many instincts relatively definite and stable which may fairly be regarded as directly due to natural selection, though here again, if we could accept the view that adaptive modification marked out the lines in which congenital variation should run, our conception of the process of their evolution would be so far simplified; thirdly, that there are some peculiar traits, also seemingly definite and stable, which can only be attributed to the indirect effects of natural selection."

In the discussion of *modifications* and *variations* the author follows Mark Baldwin in defining the former as acquisitions which occur in the course of individual life, and the latter as those changes in the individual which are the result of some disturbance in the germinal substance. Mental phenomena are laid aside for a time and the more easily apprehended arguments and illustrations from structure adopted. The author dwells at considerable length upon the claims of the extreme Neo-Darwinians, on the one hand, and the extreme Neo-Lamarckians, on the other, and concludes that "all this is very interesting, and affords considerable scope for ingenuity. But it does not touch the question at issue, and this is, not which method is apparently the most advantageous; not which method we should have adopted had the work of creation been entrusted to our care, but which has been adopted by nature." Weismann's principles of *germinal* and *intra-selection*, Baldwin's *organic selection* and the author's *innate plasticity* indicate the neutral ground where selectionists may meet transmissionists; where fortuitous variations may finally take the place of mere temporary adaptive modifications.

Professor Morgan's entertaining style, his originality of experiment, his quick interpretation, his rare quality of explanation and the comparative novelty of his subject will give 'Habit and Instinct' a place beside 'Animal Life and Intelligence' in the library of every working biologist. HERMON C. BUMPUS.

Das Nördliche Mittel-Amerika, nebst einen Ausflug nach den Hochland von Anahuac. Von DR. CARL SAPPER. Braunschweig, Vieweg und Sohn. 1897. With maps and illustrations. Pp. 436.

The studies of Central American geography and ethnography which Dr. Sapper has contributed to *Petermann's Mittheilungen*, *Globus* and other periodicals, from time to time during the last ten years, have made his name familiar to all interested in the products and history of that portion of our continent. In the volume

before us he has gathered many of these articles together, added others not heretofore published, and appended thirty pages of vocabularies of the native tongues, specimens of Indian music and various statistical matter (rainfall, culture products, etc.).

The descriptions of travel and of the manners of the present inhabitants are vivid and well told, but for scientific purposes the articles on the native population will have the higher interest. These embrace a discussion on the independent native States in Yucatan, the commercial relations of the Indian tribes in northern Central America, the present Indian geographical names in the same area, the ruins of aboriginal towns and fortresses there found, the music and dances of the existing tribes, and special articles on the Lacandons and Kekchis, two branches of the Maya family which Dr. Sapper had unusual opportunities to observe.

The information he gives on all these subjects is abundant and drawn from his own studies. Especially his article on the architectural principles indicated in the ancient ruins, and the connection of the culture areas which they indicate, is replete with new and instructive suggestions. It is amply illustrated by a number of designs in the text.

The maps are eight in number and show respectively the location of volcanoes, the distribution of vegetation forms, the elevation of land, the cultivation of commercial plants, the extension of languages, the independent Indian tribes, the native names and the ancient ruins of northern Central America.

In the final paper of the volume the author ventures on the important question as to the original seat of the Mayan culture and language. He gives substantial reasons for saying it was *not* Yucatan, which peninsula he thinks was first occupied by the Mayas about the fifth century of our era; nor was it Guatemala, Tabasco, or the territory of the Huastecas, north of Vera Cruz; but most likely the highlands of Chiapas (in which he agrees with Dr. Schellhas). He considers the adoption by the Mayas of a sedentary and agricultural life to date from a remote antiquity, and conclusively disproves the prevalent notion that it was originated or deeply modified by either 'Toltecs' or Nahuas.

The extended vocabularies include a large number of 'culture words' from the Mayan dialects, and were in great part collected by himself. They add considerably to the value of this excellent work.

D. G. BRINTON.
UNIVERSITY OF PENNSYLVANIA.

Wild Neighbors. By ERNEST INGERSOLL. New York, The Macmillan Co. 8vo. Pp. xii+301. 29 illustrations. $1.50.

Mr. Ingersoll's 'Wild Neighbors' are some of our native mammals, the red and gray squirrels, panther, coyote, badger, porcupine, skunk, woodchuck, raccoon, and incidentally many others, with which the author endeavors to make us better acquainted through interesting accounts of their habits. The biography of each species contains some descriptive notes and extended life histories, covering general habits, distribution, economic importance, and comparison with other species. The skunks of the genus *Mephitis* are compared with the mink, the European polecat, the stinking badger of East India, the honey badgers of South Africa, and our more closely related genera, *Conepatus* and *Spilogale*. One chapter is devoted to 'the service of tails, their use and importance to various creatures,' and is extended to include birds, reptiles, insects and crustaceans, as well as mammals. One is given to animal training and animal intelligence and deals mainly with domesticated species and those of the menagerie, discussing their capacity for learning.

The work brings together many interesting facts from the lives of our best known mammals in a popular style, with technicalities carefully omitted. To those who have had little to do with mammals or mammal literature it will prove new and interesting, a great part being taken by direct or indirect quotation from the works of Audubon and Bachman, Kennicott, Lord, Goode, Thoreau, Burroughs, Coues, Allen, Roosevelt, Merriam, Hornaday, Bicknell and many other well known authors. Unfortunately, however, less reliable sources have been drawn upon also and many misleading statements are made. The reader is told that the Eastern chipmunk (*Tamias striatus*) is now conceded to be the only species ranging between the Atlantic and

Pacific coasts, while in reality some 22 species and 12 subspecies are now recognized in the United States. The nuthatches are erroneously classed with the woodpecker as birds that use their tails for support in climbing over the trunks and branches of trees. Young opossums are said to go about clinging to their mothers' tails soon after they are born.

The book contains much that is good in its way; but unless the reader exercises more knowledge of mammals than the author seems to possess, he will be unable to decide what should be accepted as reliable and what rejected as unreliable. To the student of mammals if offers nothing in the way of new and original matter. The nomenclature is out of date, a large proportion of the generic and specific names differing from those in present use.

The author has experienced the usual difficulty in obtaining illustrations of mammals. The few that appear to be new are evidently taken from badly mounted specimens and are wretchedly drawn. The reproductions from previous works are not the best that might have been selected, and in most cases the reader is left to guess where he has seen them before.

VERNON BAILEY.

SOCIETIES AND ACADEMIES.

BOSTON SOCIETY OF NATURAL HISTORY.

A GENERAL meeting was held November 17th, seventy-one persons present. Dr. B. L. Robinson spoke of the flora of some of the islands of the Pacific, noting the various classifications of islands proposed and mentioning examples of the different classes. Insular floras show a paucity of species compared with genera; Leguminosæ are rare on oceanic islands. Dr. Robinson sketched the history of botanical exploration of the Galápagos and prefaced the result of his work upon the collections of Dr. Baur with an account of the classic studies of Hooker and Andersson. The flora of the upper, moister portions of the Galápagos is closely related to floras of Central America, Mexico and the West Indies, while in the lower, or desert portions, the flora has been derived from Peru and Chili. Dr. Robinson also gave a brief account of the flora of some of the Californian islands, and mentioned their resemblance to the flora of the Galápagos in the number of endemic types. The study of the flora of the Californian islands confirms Le Conte's theory that they were united with the main land up to Quaternary times.

Professor A. E. Verrill discussed the causes that determine the flora and fauna of the smaller islands off the New England coast, referring particularly to the Thimbles and other islands in Long Island Sound. The islands north of Cape Cod differ from those south of the Cape, though both are governed by the same principles; compared with the mainland the animals are few in number. The meadow mouse, *Arvicola sp.*, is the most important factor in regard to the flora, though the introduction of sheep and goats does much to change the vegetation. Many birds found on the Thimbles do not breed upon them. Reptiles are entirely wanting, and when introduced do not survive. With the exception of the red-backed Salamander, *Plethodon*, there are no Amphibians; the *Plethodon* is abundant and is frequently found associated with marine Crustaceans. The surface soil, though rich and black, did not originally contain earthworms; introduced later, they are now abundant. The larvæ of Scarabæidæ and Myriopods belonging to *Spirobolus* and *Polydesmus* were exceedingly abundant and replaced the earthworm. The *Polydesmus*, owing to the lack of fresh water and to the effect of salt water, is now extinct on the Thimbles. With insects the number of species is small; they swarm more rapidly and are more injurious than on the mainland. Of the Mollusca, two *Helices* and a *Succinea* abound; slugs are wanting. The plants are the same as those of the mainland, but only a limited number can withstand the adverse conditions caused by the salt spray, ravages of mice, drought, action of storms, etc. Certain plants are more hardy, grow more rapidly and flower more abundantly than the same species on the mainland.

Professor Verrill showed a number of drawings of marine invertebrates; painted in oil directly upon tiles and ground-glass tablets, they are helpful for purposes of museum illustration.

SAMUEL HENSHAW,
Secretary.

GEOLOGICAL SOCIETY OF WASHINGTON.

AT the 68th meeting held in Washington, D. C., November 24, 1897, Mr. M. R. Campbell made a brief informal communication on the Laminated Clays of Teay Valley, W. Va., and their origin and significance. The problem is but part of the broader problem of the physiography of that portion of West Virginia, which it is proposed by Mr. Campbell to consider on a future occasion.

Mr. J. S. Diller followed with a communication on 'The Origin of Camas Swale.' One of the principal tributaries of the Umpqua River in southwestern Oregon is the Calapooya. It rises upon the western slope of the Cascade Range, and near the eastern escarpment of the Coast Range enters the Umpqua River, which, in a remarkably meandering canyon, passes through the mountains to the Pacific. The general direction of the Calapooya is southwestward, parallel to the strike of the rocks, but nearly midway in its course it turns sharply to the northwest, and for four miles cuts directly across the general trend of the ridges and valleys. At this sharp turn heads a broad, shallow valley, known as Camas Swale. Its bottom is a plain stretching to the southwestward for about seven miles, with a width of from one to two miles. The swale is drained by Wilbur Creek, a small stream which enters the north fork of the Umpqua and for the greater part of its course is dry in summer. Camas Swale and much of the valley of Wilbur Creek, is larger than one would expect as the work of so small a stream, when compared with that accomplished by other streams of equal size in the same region.

The relation of Casmas Swale to the Calapooya suggests that it may once have been the bed of that stream. The principal flood-plain of the Calapooya is continuous with that extending through Camas Swale, and the pebbles of the bed of Wilbur Creek in the swale are largely volcanic rocks, such as could have been brought from the Cascade Range only by the Calapooya River. The size of the swale, too, bespeaks the action of a stream like the Calapooya, so that the evidence is quite clear that the Calapooya once flowed through Camas Swale, and by way of Wilbur Creek entered the north fork of the Umpqua.

Why did it change its course? The reason is to be found in the relation of Oldham Creek to the original course of the Calapooya. Along Camas Swale the two were originally parallel for a number of miles and separated by only a narrow ridge of sandstone. Oldham Creek reached the Umpqua by a direct course in six miles, while the water of the Calapooya, to reach the same point, had to travel twenty miles. Consequently, Oldham Creek, having the greater declivity, cut down its bed more rapidly than the Calapooya and enabled one of its side streams to cut through the dividing ridge and tap the Calapooya at the head of Camas Swale, thus diverting the waters of the Calapooya to their shorter course and leaving Camas Swale to be drained by Wilbur Creek, the beheaded portion of the ancient Calapooya.

W. F. MORSELL.

U. S. GEOLOGICAL SURVEY.

ENTOMOLOGICAL SOCIETY OF WASHINGTON, DECEMBER 2, 1897.

DR. F. C. KENYON, Washington, D. C.; Mrs. Annie Trumbull Slosson, New York city; Mr. R. J. Weith, Elkhart, Ind., were elected members. Officers for 1898 were elected as follows: President, Mr. H. G. Hubbard; Vice-Presidents, Dr. T. N. Gill and Dr. H. G. Dyar; Corresponding Secretary, Mr. Frank Benton; Recording Secretary, Dr. L. O. Howard; Treasurer, Mr. E. A. Schwarz.

Mr. Hubbard exhibited specimens in all stages of *Dinapate wrightii*, a very large and very rare Bostrichid beetle, the habits of which were not previously known, and which, in fact, was described from a fragmentary specimen only. Mr. Hubbard finds that this insect breeds in the trunks of *Washingtonia filifera* in southern California. He considers that the species is rapidly approaching extinction and calls it the Dodo of beetles.

Mr. Cook exhibited a new genus of Schizonotidæ, a family related to the whip-scorpions and at present containing two genera—*Schizonotus* and *Tripeltis*. The new form was discovered by Mr. Hubbard in Arizona and is distinct from others in containing two small

wedge-shaped sclerites in the transverse fissure of the cephalothorax. Mr. Cook dedicates the genus to Mr. Hubbard and the species may be called *Hubbardia pentapeltis*.

Mr. W. G. Johnson read a paper on Isaac P. P. Trimble, economic entomologist, giving an account of Mr. Trimble's life and exhibiting photographs taken at different ages and a large series of unpublished plates prepared under Mr. Trimble's direction for a second volume of his work on fruit insects. The plates excited considerable interest from their excellence.

Dr. Dyar presented a note on an external feeding hymenopterus parasite. This is a new species of the Ichneumonid genus *Pammicra*, which lays its eggs on a Nematine saw-fly larva, feeding upon black oak on Long Island. The parasite paralyzes the larva with its sting, lays two eggs upon its dorsum, and the parasitic larvæ feed externally, remaining in the larval condition five days.

Mr. Ashmead read portions of a systematic paper on the genera of the Eucharidæ and presented a new classification of the old family Chalcididæ, which he will make a super-family, Chalcidoidea, containing fourteen families.

L. O. HOWARD,
Recording Secretary.

TORREY BOTANICAL CLUB, OCTOBER 12, 1897.

No regular program had been prepared for this meeting, but notes detailing some results of summer's work were presented by Drs. Rusby and Underwood, Mr. Van Brunt, Mrs. E. G. Britton, Judge Brown, Mr. Eugene Smith, Mr. M. A. Howe and Miss Ingersoll.

Dr. H. H. Rusby spoke of his work at the Kew Herbarium in identifying some 2,000 plants of two Bolivian collections. As an indication of how the Columbia University has grown in the last few years, he noted that in working up a similar collection four years ago he was able to determine but 5 or 6 % by comparison with the plants in this herbarium, while of the present collection nearly 50 % were identified by this means. He added that the herbarium at Kew is also growing rapidly, and in four years has added to its collections nearly half as many specimens as are in the Columbia Herbarium. Dr. Underwood remarked that the Kew Herbarium is superior to the Paris Herbarium even in the plants of the French provinces. Of these, many are represented at Kew and not at all at Paris.

Mr. Cornelius Van Brunt spoke of his journey to the Selkirk and Rocky Mountains of British America, making many photographs of new or interesting plants.

President Brown described a precipice in the Shawangunk with an altitude of 2,200 feet, bearing pine trees on its summit only six inches high but with perfectly developed cones. Throughout the region *Arenaria Groenlandica* was abundant in bloom from June to September, most copiously in July. He remarked upon the abundance and profuse bloom of *Gentiana quinquefolia*, *Kalmia latifolia*, *Rhododendron maximum*, *Ilex montana* and the *Rhodora*.

EDWARD S. BURGESS,
Secretary.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of Science of St. Louis on the 6th of December, 1897, fifty persons present, Mr. Julius Hurter exhibited specimens of a considerable number of reptiles and batrachians, mostly of Southern origin, which had been collected by him during the past season, and were additions to the known fauna of Missouri. Among the more interesting additions were the cotton-mouth moccasin, the banded water snake, Holbrook's water snake, the little brown snake, the Louisiana mud turtle, the chestnut-backed salamander (first detected west of the Mississippi River by Mr. Colton Russell), and the marbled salamander.

Mr. H. von Schrenk exhibited a series of specimens and drawings illustrating some of the injuries inflicted on the trees of St. Louis by the tornado of May, 1896, showing not only the formation of double twig elongation and growth rings, but the exfoliation of the bark and the consequent drying-out of fifty per cent. or more of the wood through the trunk and branches in several species.

One new member was elected, and one person was proposed for active membership.

WILLIAM TRELEASE,
Recording Secretary.

MSS. intended for publication and books, etc., intended for review should be sent to the responsible editor, Prof. J. McKeen Cattell, Garrison-on-Hudson, N Y.

THE FOUNDERS OF GEOLOGY.

THE geologists of America in April of the present year welcomed to this country Sir Archibald Geikie, the distinguished Director-General of the Geological Survey of Great Britain and Ireland, on the occasion of his coming to give the opening course of lectures upon the George Huntington Williams memorial foundation at the Johns Hopkins University. The many representative men from all portions of America who went to Baltimore to listen to him shows the high position of authority which he holds in geological science and the desire which was universally felt to do honor to the man. Those who met him and listened to his carefully prepared words gained an inspiration which will be long felt in geology on this side of the Atlantic.

The lectures, which have been recently printed, appear in an attractive form from the Macmillan press.* In the introduction to the *first* lecture of the course the author states that the searcher after truth is liable to lose sight of the paths already trodden, and that it is, therefore, "eminently useful now and then to pause in the race, and to look backward over the ground that has been traversed, to mark the errors as well as the successes of the journey, to note the hindrances and the helps which we and our

* *The Founders of Geology*, by Sir Archibald Geikie, X. 297 pp. 1897. Macmillan & Co., London. The Macmillan Company, New York.

predecessors have encountered, and to realize what have been the influences that have more especially tended to retard or quicken the progress of research." For that purpose the epoch which extends from the middle of the last century to the earlier decades of this is especially selected as the period when the real foundations of geology were laid, although it is freely recognized that many honored names in the domain of the science antedated this time.

After referring to the curious coincidence of the appearance of the writings of the two last and most eminent of the cosmogonists, Leibnitz and Buffon, in the same year during the middle of the last century, the author proceeds in most interesting manner to describe the life and work of the hitherto little recognized Guettard (1715–1786), who, by his brilliant researches in many lines, may be truly called one of the founders of modern geology. To Guettard we owe the first practical attempt to construct geological maps by depicting the superficial distribution of mineral substances. It is doubtful, however, if he had very definite ideas regarding the sequence of formations or of geological structure. His map of western Europe, so far as it relates to the areas of his own observations in France, coincides in a broad way with the modern conception of the distribution of the stratigraphical series, although often erroneously grouping younger with older deposits in his 'bands.' Guettard's contributions in the field of paleontology are also of much significance. He recognized the importance of fossils in geological research, and published many large and elaborate memoirs in which numerous forms are figured and described. He was the first to recognize *trilobites*. The excellence of his descriptions and drawings entitle him to rank according to the author as 'the first great leader of the paleontological school of France.' His memoir 'On the Accidents that have befallen Fossil Shells compared with those which are found to happen to Shells now living in the Sea,' which appeared in 1765, is regarded as unquestionably one of the most illustrious in the literature of geology, as it introduces a natural explanation for the phenomena of organic remains entombed in the rocks.

To the field of physiographic geology his memoir 'On the Degradation of Mountains effected in Our Time by Heavy Rains, Rivers and the Sea' contributed much and must be regarded as one of the classics of that department of the science. No one had elaborated the subject so fully as he at that period.

The recognition by Guettard of the volcanic origin of the mountains of the Auvergne affords one of the most interesting chapters in the whole book. It is one of the curious facts connected with his remarkable career that these views "practically started the Vulcanist camp, and his promulgated tenets regarding basalt became the watchword of the Neptunists." It seems that he was "an indefatigable and accurate observer who, gifted with a keen eye, well-trained powers of observation, and much originality of mind, opened up new paths in a number of fields which have since been fruitfully cultivated, but who rigidly abstained from theory or speculation."

In the *second* lecture the author discusses the rise of volcanic geology as shown by the work of Desmarest, and also the beginning of geological travel by Pallas and de Saussure. To Desmarest (1725–1815), a public official and astute scientific observer, we owe a further elucidation of the geology of the classic volcanic district of the Auvergne, which had been the scene of so much of Guettard's labors. Although Guettard had observed the general volcanic character of the district, it was Desmarest who, in great detail, traced out the disposition of these various rocks and others, unrecog-

nized by his predecessors, and who endeavored to establish a system of succession among them. This led him to a study of the denudation which the several lava streams had suffered, and thus to the most comprehensive statement of the effects of erosive action based upon concrete examples which had up to that time appeared. One of the most important conclusions of Desmarest's investigations in the Auvergne was the recognition that basalt was of eruptive origin, although he found few supporters for his views and did not enter later into the prolonged discussion which arose upon the subject. His map of the Auvergne elaborated in great detail, although unpublished at the time of his death, may still be regarded as his greatest contribution to geology, and was certainly far in advance of any other attempt at the cartographic representation of geological phenomena of its day.

Desmarest also contributed four massive volumes upon Géographie Physique in the famous Encyclopédie Méthodique, and had not completed the last at the time of his death in his ninetieth year. Cuvier, in his biographical sketch of him, says: "The Academy of Sciences saw in him, as it were, the monument of a bygone age, one of those old philosophers, now too few, who, occupied only with science, did not waste themselves in the ambitions of the world, nor in rambling through too wide a range of study, men more envied than imitated."

A factor which added much to the advance in scientific thought of last century was the rise of the spirit of scientific travel. To Pallas (1741–1811), who spent six years, from 1768 on, at the head of a scientific expedition commissioned by Empress Catherine II., we owe much important geological information regarding a portion of the world then but little known. His study of the Ural chain led to his attempt to classify the rocks of mountain areas, the chief value of his observations lying "in his clear recognition of a geological sequence in passing from the center to the outside of a mountain chain. He saw that the oldest portions were to be found along the axis of the chain, and the youngest on the lower ground on either side." One of the geological questions which especially occupied his attention was the occurrence of the remains of the fossil elephant, rhinoceros and buffalo throughout the whole vast basin of Siberia, between the Ural and Altai mountains.

Few men have better claim to be regarded among the founders of geology than de Saussure (1740–1799), who was the first to arouse the modern spirit of mountaineering, and whose indefatigable travels throughout the high Alps contributed so largely to the stock of ascertained fact which was so useful as a basis for theoretical speculation. To de Saussure we owe the first use of the terms geology and geologist, while his experiments upon the fusion of rocks, although only negative results were obtained, are especially interesting, as they mark the earliest beginnings of experimental geology.

The *third* lecture deals with the history of the doctrine of geological succession, and the influence of Wernerianism upon the geological thought of the day. Lehmann, Fuchsel and Werner more than any others during the latter half of the last century advanced the ideas of geological succession. Lehmann (died 1767) published, in 1756, the first treatise in which a definite attempt is made at a chronological classification of the rocks of the earth's crust. He recognized, from a study of the rocks of the Harz and Erzgebirge, three major orders which became the Primitive, Secondary and Alluvial divisions of the proposed classification. His profiles of the succession of strata showed, according to the author, 'a remarkable grasp of some of the essential features of tectonic geology.' Contemporary

with Lehmann was Fuchsel (1722–1773), who in 1762 published one of the most remarkable works, with map and sections, which had 'up to that time been devoted to the description of the actual structure and history of the earth.' 'He recognized as clearly as Lehmann, and with more accuracy of detail, the sequence of stratified rocks,' and considered that 'the changes which the earth had undergone were of no abnormal kind.' In divining with singular sagacity 'that a continuous series of strata of the same composition constitutes a formation, or the record of a certain epoch in the history of the globe,' he anticipated, according to the author, 'a doctrine which afterward took a prominent place in the system of Werner.'

The most notable figure in the mineralogical and geological arena during the last quarter of the last century and the early years of this was Werner (1749–1817), who, chiefly by the vast influence of 'his personal gifts and character,' wielded an overmastering power upon the geological opinions of the time. Appointed professor at twenty-five in the Mining Academy of Freiberg, he gradually, by the brilliancy of his teaching, drew about him an enthusiastic body of pupils from all portions of the civilized world, and raised the local mining school into the position of a great university. "No teacher of geological science," says Geikie, "either before or since has approached Werner in the extent of his personal influence or in the breadth of his contemporary fame." His most distinguishing quality, he states further, was 'his overmastering sense of orderliness and method,' which made his contributions to the then half chaotic science of mineralogy of vast significance, although he wholly ignored crystalline form in his classification. In the study of the earth, for which he and his adherents used the term geognosy, he endeavored to apply the same precision, and laid down doctrines which he dogmatically applied, although there was generally no basis for them in observed fact. He adopted the idea that "the whole globe had once been surrounded with an ocean of water, at least as deep as the mountains are high, and he believed that from this ocean there were deposited by chemical precipitation the solid rocks which now form most of the dry land." His order of sequence, taken to a considerable extent from Lehmann and Fuchsel, was developed into a system of his own. He believed basalt and other eruptive rocks to be of aqueous origin, and all volcanic activity modern phenomena, produced by vast repositories of inflammable matter.

The greatest service which Werner rendered to the cause of geological science, according to the author, was the enthusiasm he inspired in so many capable men. Among the most distinguished of Werner's pupils were d'Aubuisson (1769–1819) and von Buch (1774–1853), who, although loyal to their master, gradually became convinced of the fallacy of many of his views, and finally practically abandoned them altogether. Curiously, they were led to these conclusions largely from a study of the district of the Auvergne, where in previous years Guettard and Desmarest had done such valuable work for the cause of geological science. Von Buch especially became one of the most prominent figures in European geology. He traveled widely, and the result of his investigations greatly enriched geological literature. In 1824 he brought out a geological map of Germany in forty-two sheets, while his contributions to the science covered nearly every branch of geological research.

The *fourth* lecture is devoted to the consideration of a very different school of geology than that described in the previous chapter. It had for a time far fewer supporters than the Neptunist System of

Werner, although in the end largely supplanting the latter. This opposing school had as its chief representative the Scotch scientist Hutton (1726–1797), who, although never wielding the personal influence of Werner, slowly developed, by actual observation, a system of geological thought that forms the basis of much of modern geology. Hutton himself published but little regarding his ideas. His chief work, entitled 'Theory of the Earth, with Proofs and Illustrations,' appeared in 1795; but Playfair (1748–1819), his friend, has given us, in his 'Illustrations of the Huttonian Theory of the Earth,' an admirable exposition of his views. Hutton, unlike Werner, had 'no preconceived theory about the origin of rocks,' but considered that 'the past theory of our globe must be explained by what can be seen to be happening now.' He observed that the greater part of the land consists 'of compacted sediment which had been worn away from some pre-existing continent, and had been spread out in strata over the bed of the sea,' and that the strata had often become 'inclined, sometimes placed on end or even stupendously contorted and ruptured.' Recognizing as of fundamental importance the internal high temperature of the globe, of which volcanoes are one of the proofs, he distinguished three types of eruptive rock—whinstone, porphyry and granite—which he considered had been intruded from below among the rocks with which they are now found associated. Hutton, to be sure, drew no distinction between mineral veins and dykes, referring them all to intrusive origin and even regarded the flint concretions of the Chalk to be of similar origin.

We find also in the Huttonian theory practically 'the whole of the modern doctrine of earth sculpture,' while there is also 'the germ of the Lyellian theory of metamorphism.' Even the modern conception of glacial action is foreshadowed in the recognition of the potency of glaciers in the transport of detritus. Hutton 'rigorously guarded himself against the admission of any principle which could not be founded on observation,' and never permitted himself to make any assumptions. It is said of him that 'he was a man absorbed in the investigation of nature to whom personal renown was a matter of utter indifference.'

Among Hutton's friends was Hall (1761–1830), to whom we owe 'the establishment of experimental research as a branch of geological investigation.' His experiments upon the fusion of rocks, in which he showed the effects of the rate of cooling upon texture, are of much interest in the history of volcanic geology. Other experiments upon the effect of pressure in modifying the influence of heat, and his machine for contorting layers of clay, are hardly less significant.

For a time the Huttonian views in Scotland received a setback by the appointment of Jameson (1774–1854), a pupil of Werner, to the professorship of geology at Edinburgh, but upon the death of the great master, in 1817, his views, already opposed openly even by some of his pupils, rapidly declined in favor, and the old controversy between the Neptunist and Vulcanist gradually disappeared.

The *fifth* lecture is devoted to a consideration of the rise of stratigraphical geology, as shown by the work of Giraud-Soulavie, Cuvier, Brongniart and D'Omalius d'Halloy in France, and Michell and William Smith in England. To Giraud-Soulavie (1752–1813) 'the merit must be assigned,' according to the author, 'of having planted the first seeds from which the magnificent growth of stratigraphical geology in France has sprung.' In a series of volumes upon the natural history of southern France, of which the first two appeared in 1780, he described the calcareous mountains of the Vivarais

and divided the limestones into five epochs or ages, the strata in each of which are marked by a distinct assemblage of fossil shells. He thought, however, "that the most ancient deposits had been accumulated at the highest levels, when the sea covered the whole region, and that, as the waters sank, successively younger formations were laid down at lower and lower levels," and "he felt confident that if the facts observed by him in the Vivarais were confirmed in other regions a historical chronology of fossil and living organisms would be established on a basis of incontestable truth."

Cuvier (1769–1832) and Brongniart (1770–1847) together studied in much detail the Tertiary formations of the Paris basin. They demonstrated in this area 'the use of fossils for the determination of geological chronology and they paved the way for the enormous advances which have since been made in that department of our science.' They brought forward clearly the evidence for 'a definite succession among the strata and the distinction of the organic remains contained in them.' Cuvier had already shown that the fossil elephant found near Paris belonged to a different species from either of the living forms, and by further research reconstructed the skeletons of other types, which enabled him to announce 'the important conclusion that the globe was once peopled by invertebrate animals which, in the course of the revolutions of its surface, have entirely disappeared.' The work of Cuvier and Brongniart upon the Tertiary formations has been but little altered, although greatly elaborated. The broad outlines sketched by them remain as true now as they were when first traced by them early in the century.

D'Omalius d'Halloy extended the work of his predecessors among the Tertiary formations, but, what is of more interest, 'recognized the leading subdivisions of the Cretaceous series and actually showed the extent of the system upon a map. This map is regarded as the first attempt to construct a true geological map of a large tract of France,' which was something more than 'a mere chart of the surface rocks.' It was provided with a horizontal section showing the structural relations of the formations.

In England, Michell is regarded as the first to present anything like a clear idea of stratigraphical sequence, a table giving the broad features of the succession of strata from the Coal Measures of Yorkshire up to the Chalk, having been drawn up by him about 1788 or 1789. Geikie very clearly points out, however, that "the establishment of stratigraphy in England, and of the stratigraphical sequence of the Secondary, or at least of the Jurassic, rocks for all the rest of Europe, was the work of William Smith," a land surveyor, usually known as the 'Father of English Geology.' "No more interesting chapter in scientific annals can be found," according to the author, "than that which traces the progress of this remarkable man, who, amidst endless obstacles and hindrances, clung to the idea which had early taken shape in his mind, and who lived to see that idea universally accepted as the guiding principle in the investigation of the geological structure, not of England only, but of Europe and of the globe." Smith made no attempt to publish his results, although he accumulated a vast store of notes upon his observations during his journeys in the pursuit of his profession. His ideas gradually became widely known, and a card of English strata from the Coal to the Chalk, drawn up in 1799, though not actually published, obtained wide publicity. His geological map of England and Wales with part of Scotland, in fifteen sheets, regarded as one of the great classics of geological cartography, and upon which he had been at work for many years, was not

published until 1815. The appearance of this map marked 'a distinct epoch in stratigraphical geology, for from that time some of what are now the most familiar terms in geological nomenclature passed into common use.' Smith also published geological maps, on a larger scale, of the English counties and a series of horizontal sections across different parts of England.

The *sixth* and last lecture deals with the further development of stratigraphical geology along lines laid down by Smith and his distinguished contemporaries, who had applied the criteria derived from fossils with such success. Smith's researches, as we have seen, did not include rocks older than the Coal Measures. The great mass of earlier strata known in the old classification as Greywacke, or Transition, rocks were regarded in their generally disturbed and poorly fossiliferous condition to be beyond interpretation by the principles of Cuvier, Brongniart and Smith, until Murchison and Sedgwick, for the most part, 'working independently of each other in Wales and in the border counties of England,' succeeded in establishing a definite order among the oldest fossiliferous formations, thus adding the Devonian, Silurian and Cambrian chapters to the geological record.

Murchison (1792–1871), after several years of investigation of the Secondary rocks of England and the Continent, and some preliminary work with Sedgwick upon the old rocks of the northern counties of England, began in 1831 in Wales and the adjoining counties of England his epoch-making study of the strata below the Old Red Sandstone. Starting with that already known and easily recognizable horizon he established a series of underlying divisions which he found to be characterized by peculiar fossils. To this assemblage of formations, which he divided into an Upper and a Lower series, he gave the name of Silurian System. He recognized its conformity to the Old Red Sandstone, but wrongly thought it to rest unconformably upon the older series of greywacke. Murchison also worked out the lithological character of these old rocks, observing eruptive materials among them, some of which he clearly saw were intrusives, while others he recognized to be lavas and ashes. His first communication upon this subject was made to the Geological Society of London in 1831, his great book, 'The Silurian System,' appearing in 1838. The author tells us that even before the advent of this volume his remarkable results had become widely known and 'within a few years the Silurian System was found to be developed in all parts of the world,' Murchison's work furnishing the key to its interpretation.

Sedgwick (1785–1873), almost from the very beginning of his career, devoted his energies to the ancient rocks, his earlier publications, however, showing strong leanings to the Wernerian school. He soon parted with these views and early came to a true perception of geological principles which he applied in a study of the older formations of northern England. The author tells us that though fossils had been found in the rocks Sedgwick did not at first make use of them for purposes of stratigraphical classification, but ascertained the succession of the great groups of strata upon lithological grounds alone. He, as well as Murchison, recognized volcanic rocks to form part of the greywacke rocks of North Wales and soon 'succeeded in disentangling their structure and ascertained the general sequence of their principal subdivisions.' At this period, however, his investigations were of far less significance in the field of general stratigraphy than Murchison's, since he had not determined the relation of his rocks to any well recognized horizon and had made no use of fossils for correlative purposes. Later investigations showed that the upper part of what Sedgwick termed the Cambrian system con-

tained the same organic remains as the Lower Silurian formations defined by Murchison, and thus arose a permanent misunderstanding between these two old friends and leaders in English geological thought.

While this dispute was in progress Barrande made his remarkable investigations in the Bohemian basin, where he not only recognized the equivalents of Murchison's Upper and Lower Silurian, but also found a still older group of strata containing forms similar to those occurring in Sedgwick's Cambrian system. To the latter fauna he gave the name of First or Primordial fauna. The consensus of geological opinion, on the grounds of priority, to-day regards as Lower Silurian the Upper Cambrian of Sedgwick. Sedgwick's classification, however, in these old and disturbed rocks has proved of vast importance in the elucidation of the ancient sediments, and the succession of strata observed by him has continued with hardly a modification to the present day.

A no less important work pursued by Sedgwick and Murchison together in the days before their estrangement was the determination of the Devonian. Its reference in the absence of stratigraphical data to a position between the Silurian and Cambrian was based mainly upon the paleontological work of Lonsdale, who pointed out that the fossils in its lower portions showed an affinity to the Silurian while those in its upper parts were closely allied to the Carboniferous faunas.

The pre-Cambrian rocks now remained to be studied and deciphered. The paleontological criteria were no longer available and many difficulties presented themselves. "The first memorable onward step," according to Geikie, "was taken in North America by Logan (1798–1875)." Some study had already been given to these old rocks, but Logan was the first to attempt to establish a chronological sequence among them. To him we owe the names Laurentian and Huronian, and although his results have been much modified by subsequent observers his work marks a distinct advance in this field of stratigraphical geology.

The first recognition of the wide significance of glaciers as geological factors of more than local importance must be accorded to Agassiz (1807–1873). He was the first to offer a satisfactory explanation for the so-called erratics, which were found distributed over the Swiss plain and the flanks of the Jura mountains. Contrary to the preconceived notions of the day, he held that the Alpine ice once extended over the area and that it was an explanation of a former period of extreme cold. His further researches in England, where he found similar phenomena, convinced him that the great extension of ice was connected with the last great geological change on the surface of the globe. These teachings of Agassiz, which to-day, in all their essential elements, have been generally accepted, place his name, according to the author, as that of 'the true founder of glacial geology.'

The attempts at geological classification upon lithological grounds, which had been pushed to such an extreme by Werner and his followers, greatly declined after the marvelous impetus which the study of organic remains brought to the science of geology. But the investigation of rocks in their mineralogical aspects was not to be permanently abandoned. The invention of the famous prisms of Iceland spar by Nicol and the cutting of thin sections introduced a new element into geological investigation, but it was not until Sorley extended this method by the more systematic examination of thin sections that microscopical petrography became recognized in the field of geological research. The publication, in 1858, of his memoir 'On the Microscopic Structure of Crystals' marks one of the most prominent epochs in modern geology. There was at first much opposition to this method

of investigation, but it soon had many devoted followers who have done much to advance the science, among the more important being Zirkel, Rosenbusch, Fouqué and Michel Levy.

There yet remain two illustrious names to be mentioned among the founders of geology. They are Charles Lyell and Charles Darwin. Lyell (1792–1875), who exercised a profound influence on the geology of his time, adopted the principles of Hutton, and with marvelous industry collected a vast store of facts in support of the doctrine that 'the present is the key to the past.' He pushed the Huttonian doctrine to its logical conclusion and became the great leader of uniformitarianism, a creed which, according to the author, 'grew to be almost universal in England during his life, but which never made much way in the rest of Europe.' Lyell's 'Principles of Geology' must certainly be regarded as one of the classics of our science. To Lyell, in conjunction with Deshayes, we owe the classification of the Tertiary into Eocene, Miocene and Pliocene, upon the basis of the proportion of living species of shells. Lyell was not so much an investigator as 'a critic and exponent of the researches of his contemporaries.' Ramsey said of him, "We collect the data, and Lyell teaches us to comprehend the meaning of them."

Darwin (1809–1882) did much, not only by his contributions to the literature of geology, but in the introduction of the doctrine with which his name is associated, to revolutionize the geological thought of his time. His demonstration of the imperfection of the geological record and the great antiquity of the earth's crust came, according to the author, 'as a kind of surprise and awakening.'

In concluding the lectures the author calls attention to three prominent facts: first, that but three of the men considered, Werner, Sedgwick and Logan, could be called professional geologists, the others being either men of leisure, as Hutton, Hall, de Saussure, von Buch, Lyell and Darwin, or professionally engaged in other pursuits, as was the case of the great majority; second, that geology affords 'some conspicuous example of the length of time that may elapse before a fecund idea comes to germinate and bear fruit,' as, for instance, the length of time taken for the true principles of stratigraphical geology to become recognized; and third, that 'one important lesson to be learnt from a review of the early history of geology is the absolute necessity of avoiding dogmatism' the examples of the Wernerian catastrophist and uniformitarian schools being cited.

In endeavoring to give a somewhat comprehensive review of this latest important work of Sir Archibald Geikie it has been impossible to bring out clearly the delightful biographical and personal touches which so charm the reader. In the summary of the work which I have given it has been my endeavor to use, so far as possible, the phrases and happy expressions with which the book so richly abounds. The volume is one of much significance to the student of geology, as it for the first time presents to English readers anything like a satisfactory statement of the development of geology. Many of the men to whom we owe so much regarding our modern views of the science, and whose work has been but little considered by recent writers, are brought before us in their true proportions. The book must take high rank among the many other masterpieces of the distinguished author.

JOHNS HOPKINS UNIVERSITY.

CHARACTERS, CONGENITAL AND ACQUIRED.

II.

ACQUIRED physical characters (properly so termed) may involve not only quantitative changes, which alone we have as yet considered, but qualitative changes also.

Here, again, a wide field for investigation presents itself. For example, in man exercise does not merely cause a muscle to increase in size; it occasions besides, as in athletes after training, an increase in efficiency (*i. e.*, in the power and duration of contraction), which is greatly out of proportion to the increase in size. Intermittent friction or heat or other irritant (*e. g.*, chemical) not merely causes the skin to thicken, as in corns and callosities; it renders it denser also. Again, stimulation (that is use) may result in change which is wholly qualitative. Thus eyes which, when unaccustomed to the task, are rendered sore by the continued scrutiny of small objects (*e. g.*, print, as in the case of an adult learner) may by practice be trained, without apparent physical change, to endure this proceeding without damage. Most of these qualitative changes are best studied in connection with mind, but there is one series, of vast importance to the higher animals, and especially to man, which is entirely physical, and to which I may, in conclusion of this part of my subject, draw attention. I allude to the power which Natural Selection has developed in high animals of acquiring capabilities of resisting various poisons, particularly those offensive and defensive poisons (toxins) which are secreted by various plants and animals. Thus men acquire greatly increased powers of 'tolerating' nicotine and opium, which are *toxins* secreted respectively by the tobacco and poppy plants to protect them from organisms to which they are liable to fall a prey. Thus also man may acquire the power of 'tolerating' the poisons of various species of parasitic micro-organisms which afflict him and the higher animals, and which are the cause of that great class of diseases known as zymotic. These toxins, also, are defensive products by means of which the pathogenic organisms ward off the attacks of the phagocytes in the blood of the host by which they are liable to be destroyed.* When the phagocytes, through experience of the toxin, acquire the power of tolerating it they destroy the microbes whereby *acquired immunity* is achieved, as in chicken-pox, measles, scarlatina, small-pox, typhoid, etc. Without this power of acquiring immunity (temporary or permanent) there could be no recovery from such a disease as measles, for instance; and therefore, since, unlike malaria, for instance, most of these diseases pass from one infected person to another, and are for that reason diseases of comparatively dense populations. Without this power of acquiring immunity no dense populations could exist. In other words, if this power of acquiring immunity had not been evolved in man, civilization would have been impossible.

I have said that the power of acquiring physical traits does not exist among low animals, or, if it exists, does so in proportion as they are lowly placed in the scale of life, to an extent very small as compared to its development among high animals. If I am right as to this, low animals (*e. g.*, invertebrates) should be incapable or little capable of acquiring immunity against zymotic disease. I am not aware, however, that any observations on the subject have been made.

I dare say that many who read the foregoing will be inclined to dispute the facts and inferences put forward, and to urge, for instance, that I have not established any proof, nor even brought forward convincing evidence, of the truth of my assertion that low animals are incapable, or less capable than high animals, of acquiring physical characters. There is, in truth, no literature to which I can appeal, for the question is

* Vide *The Present Evolution of Man*, pp. 199–32 (London, Chapman & Hall, 1896), and an 'Address on Acquired Immunity,' by the author, *Lancet;* September 11, 1897.

entirely new; and therefore, also, so far as I am aware, no experiments directly bearing on it have been made. Moreover, in the highest animals all acquired physical characters are merely extensions of previously existing inborn characters. Thus the limb of an infant, which is compounded, as we may suppose, almost entirely of that which is inborn, grows under the influence of exercise and use into an adult limb. There is a sharp dividing line, but we cannot perceive it; and, therefore, as regards the infant's limb, we cannot as yet say where the inborn ends and the acquired begins. But in mind, which we have next to consider, the case is often very different. There the inborn is often sharply marked off from the acquired, and we shall find it emphatically true that low animals are infinitely less capable of acquiring mental traits than high animals. Whence, reasoning by analogy, we may, with some confidence, assert that if, as regards mind, the statement is true, in the absence of evidence to the contrary, it is probably true also as regards the physical parts.

Mind, doubtless, owes its origin to movement—to the necessity for coördinated movement in the various parts of the complex cell-community which we call a multicellular animal. Neither mind nor nervous tissue, the organ of mind, exists in plants, among which there is little or no movement. So, also, low in the animal scale, as among sponges, in which cells are not coördinated to perform movements *en masse*, there is no mind nor any need for it. Higher in the scale, as among Cœlenterates, in which masses of the cells combine to perform macroscopic movements, we begin to find traces of nerve tissue, but as yet there is, so far as we are aware, no mind. All movement apparently is purely reflex. Yet higher in the scale, as among the Mollusca in which the increasing complexity of the environment necessitates increasingly complex coördinated movements of masses of the cell-community, the nervous mechanism by means of which this coördination is carried out becomes still more developed and complex, and mind apparently dawns. So far as we know, consciousness then first appears, and with consciousness the rudiments of instinct.

I have elsewhere defined instinct as "the faculty which is concerned in the conscious adaptation of means to ends by virtue of inborn inherited knowledge and ways of thinking and acting."* In other words, instinct depends wholly on congenital characters, and not in the least on those which are acquired. This definition of instinct is far different from those which have hitherto found acceptance, but I think on consideration it will be found that it more correctly describes what we commonly mean by the term than any other hitherto put forth. By instinctive action do we not mean action which is independent of all previous experience and therefore of acquirement? When an insect secures its proper food in the proper way, spins a cocoon, mates with an individual of the opposite sex, or lays its eggs, with fit provision for the future, in an appropriate place, does it not act solely by virtue of inborn inherited knowledge and ways of thinking and acting, and, since it is unguided by experience, not in the least by virtue of knowledge and ways of thinking and acting which are acquired? To the mind of every naturalist will at once occur innumerable instances of actions, some of them extremely complex and elaborate, performed by insects and other comparatively low animals, in which experience can play no part; in other words, which are wholly independent of acquired knowledge and ways of thinking and acting. By means of instincts animals are enabled to place themselves in harmony with an environment infinitely more complex than

* *The Present Evolution of Man*, p. 137.

that to which reflex action alone can adapt them. The element of consciousness and its outcome, choice, are introduced. The conscious animal, unlike the unconscious, is enabled to choose between two or more courses, to which two or more instincts impel him. Thus the male spider approaches the gigantic female, guided by both the mating and life-preserving instincts, and all the complications of his subsequent conduct are due to his power of choice between two or more courses.

Higher in the scale, concurrently with the evolution of the power of acquiring physical traits (properly so called), is evolved the power of acquiring mental traits. It increases in successively higher animals, and at length, in the highest animals, becomes of such importance that it overshadows and replaces instinct, which, since it no longer holds a commanding place as a factor in survival, undergoes great retrogression.* If I can make my readers grasp all that is implied in the above I think they will admit the vast importance I have claimed for my subject—an importance which is not only from the standpoint of the man of science, but from many other standpoints, such as those of the moralist, the sociologist, the statesman, the philanthropist, the physician and others as well.

Let us contrast two animals which, for convenience, we may regard as at opposite ends of the scale, the dragon-fly and man. Tennyson's beautiful lines occur to me. I quote from memory :

> To-day I saw the dragon-fly
> Come from the wells where he did lie.
> An inner impulse rent the veil
> Of his old husk. From head to tail
> Came out clear plates of sapphire mail.
> He dried his wings ; like gauze they grew.
> O'er crofts and pastures, wet with dew,
> A living flash of light he flew.

Physically, like other low animals, the dragon-fly does not develop in response to exercises and use, or, if he does, it is to a very small extent compared to higher animals. Natural selection has nicely coördinated his structures, but has not evolved in them (at least to an appreciable extent) the power of developing further and in the right direction during the changing stress of circumstances. For example, his principal organs of locomotion, his wings and the structures which subserve them, are certainly wholly inborn. Mentally, at the beginning of each stage of his existence he is able to coördinate his muscles perfectly, and thus at the beginning of each stage his locomotion is apparently as good as at the end. Both in the water and in the air he knows what food to seek, and what enemies to avoid, and how to do so. At the fit time, impelled by an inborn impulse, he leaves the water, and, having undergone his last metamorphosis, is able, at once, to adapt himself to life in an entirely new environment, where the medium in which he exists, his mode of locomotion, his prey and his enemies are different, and where his procreating instinct comes into activity. But experience teaches him little or nothing; he cannot acquire mental traits; in other words, *he has little or no memory.*

Far different is the case with man. We have seen how much he acquires physically, so that the adult differs from the infant mainly in traits which he acquires, not in those which are inborn. Mentally, his powers of acquirement are even more remarkable; and, therefore, even more as regards his mental characters than as regards his physical characters, the adult differs

*Just as physical characters (*e. g.*, limbs of serpent, lost digits of horse, eye of proteus) undergo retrogression through atavism, wherebymore and more remote ancestral conditions are reverted to till that remote ancestral character is reverted to, when the character did not exist. Vide *The Present Evolution of Man*, pp. 18–30.

from the infant in that which is acquired, not in that which is inborn. At birth the infant's mind is a blank; he can coördinate only a very few groups of muscles (*e. g.*, the breathing, sucking and defæcating groups), and in these the coördination is never very delicate and elaborate. He knows nothing of his environment; he cannot, as can the dragon-fly, instinctively adapt himself to it. But gradually as his body develops under the influence of use and exercise, his mind develops also under the influence of experience, and the blank left by the retrogression of instinct is filled and more than filled by acquired knowledge and ways of thinking and acting. Slowly and painfully the infant *learns* to coördinate his different groups of muscles till at length he can perform such complex acts as speaking, writing and walking in which the coördination is exceedingly delicate and elaborate.* Much, very much, besides the power of coördinating his muscles is acquired by man. For instance, all the vast contents of his memory and all that arises out of memory are, of course, acquired. Here, again, all that is inborn is *the power of acquiring the contents of the memory*. I have elsewhere defined reason as 'the faculty which is concerned in the conscious adaptation of means to ends by virtue of acquired non-inherited knowledge and ways of thinking and acting.'* Compare, for instance, the construction of a cocoon by a caterpillar, or the first web spinning of a spider, to the construction of a house or the weaving of a net by a man. In the absolute absence of experience the caterpillar and the spider plainly act by virtue of inborn knowledge and ways of thinking and acting, in other words, by instinct; the man, on the other hand, as plainly acts by virtue of acquired knowledge and ways of thinking and acting, in other words, by reason.† In fact, so vast a part does the

*It has been denied (*e. g.*, *Lancet*, May 1, 22 and 29, 1897) that speech and bipedal progression are acquired. The denial arises from that habit of thinking in abstract terms which is the bane of many writers. One cannot speak without words, and every word is acquired and, therefore, speech itself is acquired. For instance, no one is born with the knowledge of the word 'brick.' Again, this sound (brick), like all others in a language, is produced by a particular and very delicate and complex coördination of the speech muscles, different from what is required to reproduce any other sound. The child *learns* to make this coördination, just as in after life he may learn to make that coördination from which results a foreign word, or that coördination of a different set of muscles from which results a written word. Again, a child *learns* to walk in just as true a sense as afterwards he may learn to bicycle. Speech and bipedal progression are common to the whole human race, and, therefore, they are invariably regarded as inborn characters. Writing and bicycling are not common to the human race, and, therefore, they are regarded as acquired; but very plainly the former are as much acquired as the latter. What alone is inborn is the *power of acquiring* speech and bipedal progression and vastly more besides.

* *The Present Evolution of Man*, p. 138.

† The terms 'instinct' and 'reason' are used very loosely even by scientific writers, the meaning of the former often being too much extended, while that of the latter is too much restricted. Thus, it is said, that we instinctively like or dislike this or that object, *e. g.*, man, implying thereby that we do so in the absence of experience. But the new-born infant (unlike the new-hatched fish) has no such instinctive like or dislike; his subsequent likings or dislikings arise as a result of experience, whether such experience remains as a recognizable part of consciousness or not. Again, actions which depend on acquirement, but which have become automatic from frequent repetition, are often termed instinctive, owing to the instinct-like absence of mental effort with which they are ultimately performed (*e. g.*, bipedal progression; vide *Present Evolution of Man*, pp. 144–5). On the other hand, the term rational is often restricted to such actions as conspicuously result from a correct chain of inferences, or to such as are not performed under the influence of violent emotion. For example, when an angry man embarks on foolish litigation we term his action irrational, thus expressly excluding it from the category of rational actions. But his action is certainly not reflex, nor, as certainly, is it instinctive, and, therefore, if we group all actions under the headings of reflex, instinctive and rational this action can belong to the last group only.

acquired factor play in all that is mental in man, that I have been unable to discover any action in him which is purely instinctive. Purely reflex actions he has in plenty, as, for instance, the movements of the various hollow viscera; but of the few instincts which survive in him (*e. g.*, parental and sexual love) none apparently are gratified without the aid of rational action. Consider, for instance, how greatly the instinctive appreciation of female beauty is modified by the acquired factor; there are savage tribes who mutilate, to render beautiful as they think, the faces of their women to a frightful degree.* Consider, again, how much there is rational (*e. g.*, the coordination of her muscles) in the mother's care of her offspring.

As in the case of physical characters, no systematic attempt has been hitherto made to differentiate between the mentally acquired and the inborn. As a result, much confusion and inaccurate thinking is manifest in writings, scientific and otherwise. I propose to deal with these to some extent presently; but first it would be interesting to trace, in however slight a manner, the evolution of the power of acquiring mental traits in animals. But, even before doing this, one other digression I may permit myself, since it has an important bearing on much that follows. It has been maintained that acquired characters, mental and physical, are transmissible. I will not here pause to consider whether such characters as I have ventured to denominate 'enforced,' nor whether such characters as result from the complete or partial reproduction of lost parts, are transmissible. The battle has been fought in countless publications, and I do not know that I have now anything very new or original to add; but I should like to say a little concerning the alleged transmissibility of such characters as result from use or experience, for instance, the acquired enlargement of the blacksmith's muscle through use, or the mental change involved in the acquirement of a knowledge of mathematics through experience. Characters like these are held by a section of biologists to be transmissible, in part at least. But when a parent acquires such characters they reappear in the child only in response to stimulation similar to that which caused them to arise in the parent. For instance, without such stimulation the child gets neither the enlarged muscles nor the knowledge of mathematics; in fact, the child must in all cases, acquire such characters afresh; from which it is plain that that which is acquired by the parent does not become inborn in the child.

It may, however, be maintained by Neo-Lamarckians that stimulation causes not only the acquirement of a character, but increases also the power of acquiring it, and that it is this increase in the parent which is transmitted to the child, and which renders more easy the acquirement of the character by the latter. But there is no tittle of evidence showing that the stimulation which results in the acquirement of a character (mental or physical) causes also an increase in the power of acquiring it. The converse is in fact true; the infant's power of acquiring characters, mental and physical, is immense, and to it is mainly owing the development he undergoes in his passage from infancy to old age; but this power steadily declines in his long stimulated parts (mental and physical), till in the old man it is reduced to a minimum and tends to vanish. Clearly, then, as regards such characters as result from use and experience there can be no transmission to the child; therefore, as regards them, evolution must have proceeded

* Our women have worn crinolines and chignons and still wear earrings and corsets.

wholly on lines of Natural Selection. Moreover, instincts (and such physical characters as are analogous to instincts, *i. e.*, inborn physical parts) cannot have resulted from the transmitted effects of experience and use, since they do not increase under such stimulation. There is, for instance, no reason to suppose that any instinct is sharpened by use, or, in other words, by experience. In fact, it would be a contradiction in terms to suppose that it is, since, if my definitions are right, all that is acquired pertains to reason, not to instinct. Moreover, did instincts increase under stimulation and were this increase transmissible in however slight a degree, then instincts should be most developed in the highest animals and less in lower animals. The contrary, however, is the fact.*

All acquired mental characters depend, of course, in the last analysis, on memory; and, therefore, an animal which is incapable of acquiring mental characters, and which, therefore, depends wholly on instinct, can have no recollection of past events, nor, as a consequence, any ideas concerning the future; it must live entirely in the present. To this it may be objected, however, that various insects display an instinctive memory, and, for instance, return again and again with food to the nest where they have laid their eggs. If, however, my definitions are correct these returns are not due to memory, but to an impulse (similar to that which causes them in the absence of experience to know a fit spot wherein to lay their eggs), which causes them again and again to return to this particular place, quite independently of any recollection of having been there before.† It has even

* It follows, then, from the above, that, except as regards the effects of mutilations, which I do not here consider, evolution can have proceeded only on the lines of inborn variations.

† Compare the swiftly forgotten alarm of a house-fly with the more and more permanent fear of successively higher creatures.

been denied that animals so high in the scale as fish possess a memory (the power of acquiring mental characters).* The seat of the memory has been held to be the cortex of the brain, and fish alone of all vertebrata have no cortex.† I think, however, there can be no doubt that fish have some power of acquiring mental traits, since trout in a much-fished stream soon grow more wary. Indeed, memory may be detected in animals much lower than the fish. Even so low in the scale as the oyster is a rudimentary capacity for mental acquirement observable, for "even the headless oyster seems to profit from experience, for Dicquemase asserts that oysters taken from a depth never uncovered by the sea open their shells, lose the water within and perish; but oysters taken from the same place and depth, if kept in reservoirs, where they are occasionally left uncovered for a short time and are otherwise incommoded, learn to keep their shells shut, and then live for a much longer time when taken out of the water."‡

As I have already said, speaking in general terms, the higher placed an animal is in the scale of life the greater is its power of acquiring mental characters, as will be apparent presently and as might have been expected; but it is also true that the higher species of a lower class or order often exhibit greater capacities for acquirement than

* Vide *Lancet*, January 23, 1897.

† And, therefore, in choosing the dragon-fly as an animal conspicuously lacking in acquired mental traits to contrast with man, in whom they are conspicuously abundant, I have not intended to imply that the former is quite incapable of acquiring mental characters, only that it is so little capable of acquiring them that it forms an admirable foil to man, the animal above all the most capable of such acquirement. I do not *know* that the dragon-fly is quite lacking in this quality, but only that it is so little developed in him that I personally, with my imperfect knowledge, have not been able to detect any traces of it.

‡ 'Animal Intelligence,' by Romanes, pp. 24, 25.

the lower species of a higher class or order. It is even true that some invertebrates exhibit far greater mental receptivity than many vertebrates. Speaking again in general terms, the power of acquiring mental characters is only developed to a considerable extent in such animals as tend their young, and in them it is developed in proportion to the length of time parental care is continued. Furthermore, it is developed to a very great extent only among such animals as not only tend their young for prolonged periods, but also lead gregarious lives. When animals, after laying their eggs, abandon them to chance it is clear in cases where mind (*i. e.*, consciousness and all that results from consciousness) plays a part in securing survival that such mind must be considerably developed from the moment of hatching. Hence it is that in such animals instinct greatly predominates. Moreover, they cannot acquire traits by imitation from their parents, and, therefore, whatever is acquired by the one generation is completely lost to the next; in other words, they have no traditional knowledge, and all that is mental in the individual is either inborn or has been discovered by himself. But when the animal, after birth, is protected for a prolonged period by its parent it is clear that instinct (inborn knowledge and ways of thinking and acting) becomes less necessary for survival, since an opportunity is afforded for acquiring fit knowledge and ways of thinking and acting from the environment, particularly from the parent. It is then possible for knowledge to become traditional, and to be handed down from parent to offspring. When, in addition, such animals lead gregarious existences the individual has the opportunity of acquiring mental characters, not only from the parent, but from other members of the community as well, and then complex mental acquirements have the best chance of being transmitted, instead of being lost. Under such circumstances the power of acquiring useful mental characters becomes a main factor in the struggle for existence, and those individuals that most possess it survive in the greatest numbers; and therefore, concurrently with the growth of knowledge, occurs an evolution of the power of acquiring knowledge and a corresponding retrogression of instinct, which, in the ancestry, was a main factor of survival, but is now no longer so.

I have given the dragon-fly as an example of an active animal which does not tend its young, and in which, therefore, instinct is developed to a high degree. The ant, on the other hand, is an animal which not only tends its young, but also lives in great communities; and we have striking evidence that some species of ants, at least, and probably all of them, are actuated largely by knowledge and motives which are acquired, *i. e.*, by reason, and not by inborn mental characters, *i. e.*, by instinct. Thus enslaved ants, captured as pupæ and educated wholly by their captors, differ markedly from the free members of the species; they have other knowledge and ways of thinking and acting; and the fact that the slaves, in their new homes, so readily adapt themselves to the changed environment, so readily exhibit knowledge and ways of thinking and acting which must be acquired and cannot possibly be instinctive, for the reason that their ancestry can never have been subjected to the influence of a like environment, proves how great a share reason has in all that is mental in them. And since the slaves clearly acquire mental traits which fit them for their duties as servants, it is not unreasonable to suppose that the slave-holders, in like manner, individually acquire the mental traits which fit them for functions as masters, *i. e.* that in them the slave-holding habit is not instinctive, but rational.

The lower vertebrata do not tend their young, which, therefore, are hatched highly endowed with instinct, but with little power of acquiring mental characters. Reptiles, having better developed brains, have greater capacities for acquirement than fish; they can be trained to a much great extent, can learn much more, and have been known to manifest affection for their masters, in which cases the acquired affection has been so strong as to overcome the instinctive dislike. Birds and mammals, like ants, tend their young, which, in proportion to the amount of protection accorded, are born helpless and devoid of instinct, but capable of mental acquirement. Ever, as we rise upwards in the scale, do we find this increasing protection associated with a growing helplessness at birth, and a steadily enlarging capacity for acquirement which finds physical expression in a more and more developed brain, especially of the cerebral portion of it. A partridge at hatching and a fawn at birth are able to coördinate their muscles to a considerable extent, and have many other instincts. The parrot and the pup are very much more helpless, but their capacity for acquirement is greater in proportion. Highest of all, the human infant is born absolutely helpless; it is unable to coördinate all but a very few groups of muscles; its instincts are reduced to a minimum; it cannot even seek the breast; but it is protected with prolonged and tender care, under which its vast powers of acquirement come into play.

Instincts, therefore, have undergone great retrogression in the higher types, but amid this general retrogression three instincts at least have undergone evolution: (1) the parental instinct to protect the offspring; (2) the parental instinct to impart to the offspring the acquired knowledge which subserved the parents' survival; and (3) the instinct which impels the offspring to imitate the parent, and so acquire the physical and the mental traits, the traditional knowledge and ways of thinking and acting, which the latter acquired. This subject is a very interesting one, but my space is limited, and therefore I will not dilate on it, but content myself by instancing such familiar examples as the hen, the cat and the human being in proof of my statements. Each of these animals teaches its young in a different way, and the instinct of the young causes it to imitate the parent and sport in such a manner as to develop (*i. e.*, favor the acquirement of) the physical and mental characters which conduce to the survival of the individual and the race. If it be doubted that animals lower than man have traditional knowledge, which is handed from generation to generation, I have only to instance parrots of New Zealand, which have recently acquired the habit of sheep eating, and the change which soon occurs in the demeanor of the higher animals towards man when he first enters a land where he was previously unknown, *e. g.*, the Galapagos Islands. In such lands lower animals (insects, for instance), if they exhibit alarm on his first appearance, show no increase of it in subsequent generations.

Some of this traditional knowledge, especially when it is of a kind greatly to favor survival, is doubtless of vast antiquity. Of such a nature, if I am right in regarding it as an acquirement, must be the slave-making habit of certain ants, since their very physical structure has been immensely modified by it—not by the *congenital* transmission of acquired characters, but wholly by the transmission and accumulation of such inborn variations as best served the utilization of the acquired character; hence, for instance, the great jaws of *F. rufescens.* In man occur many examples of physical structures modified by the persistent acquirement, in generation after generation during long ages, of particular acquired characters. For example, his whole di-

gestive apparatus has been modified by his acquired habit of cooking or otherwise modifying his food, to which cause may even be attributed the unsoundness of the teeth of civilized man; these, since they are no longer absolutely essential to survival, having undergone retrogression as regards their power of resisting bacteria, etc. His lingual muscles have been modified by his acquired habit of speech. His slowly-acquired habit of bipedal progression has resulted in immense and obvious physical alteration. Even the acquirement of surgical knowledge, at first rudimentary, but now highly advanced, has caused at least one important modification. Animals, as a rule, bear their young easily. When any disproportion exists between the fœtal head and the maternal pelvis both mother and offspring perish and the peculiarity is not transmitted. Savage women are under much the same conditions, and give birth almost as easily as lower animals. But for ages civilized women in labor have received artificial aid; they are, therefore, nearly all incapacitated for a time after the birth of each child; indeed, the recent advance of obstetric science has enabled so many of the otherwise unfit to survive among us for some generations past that now numerous women are quite unable of parturition without instrumental aid.*

The evolution of the power of acquiring characters, mental and physical, appears to me the most important, indeed the very central fact in the evolution of all the higher animals. Beyond all other characters this has been steadily evolved by Natural Selection, and therefore the higher placed an animal is in the scale of life the more is it developed in him. Possibly some other mammals are as capable of acquiring physical characters as man; it may be that as much of the physical development they undergo after birth is due to the effects of use and exercise; but, beyond question, no other animal is mentally so receptive as man. His power of acquiring mental characters (*i. e.*, his memory) is enormous, and so greatly does he depend on it for survival that, as we have seen, his inborn mental characters (*i. e.*, his instincts), except in a few instances, have undergone complete retrogression. His mind, as I have said, is a blank at birth, and it follows, since so much is acquired, that the disposition or character of every man must be almost entirely acquired, and not inborn, as is usually assumed. Part of the contents of his memory are recognizable (*i. e.*, may be distinctly remembered), but very much, especially all that is acquired during infancy, is not so. We speak of it as 'forgotten,' but forgotten things, though they can no longer be represented in consciousness, yet leave their impress on the mind. To take an illustration: imagine twin infants in the same cot, one awake and the other asleep; suppose an event happens that alarms the waking child, but leaves the other unaffected; suppose, again, that subsequently another event, observed by both children, occurs, which, owing to the apprehension and nervous irritability engendered by the previous event, again alarms the first child, and thus increases its irritability, but, because of its previously undisturbed equanimity, again leaves the second unaffected by fear; imagine this process repeated; then, though the original cause of fear were quite forgotten, the one child might well grow up of a much more timid and

*The use of forceps was formerly very rare in midwifery practice, but is now very common. Doubtless this is mainly due to a change in fashion, the modern obstetrician, on the average, being more skilful and, therefore, more ready to use his instruments than his forebear; but, doubtless, also, it is due in part to a growing disproportion between the maternal pelvis and the fœtal head in highly civilized races. It is not possible that the saving of so many narrow-hipped women and big-headed children can have left the race unaffected.

nervous disposition than the other; in which case every one would speak of the former as *naturally* (*i. e.*, innately, instinctively) more timid than his brother, though, in fact, his excess of timidity would be acquired.

In practice, owing to the necessity of the case, we act as if we realized that man's mind, his character, his disposition, is almost entirely acquired; and, therefore, every parent carefully trains his child for a prolonged period, striving by precept and example to inculcate fit mental traits, that is, fit knowledge and ways of thinking and acting. Even the savage mother does this, and civilized nations have vast state establishments for educating their youth. Moreover, we realize that a child reared by the brave or the cowardly, the active or slothful, the moral or the immoral, the patriotic or the non-patriotic, the devout or the sceptical, and so forth, will exhibit the traits of his educators, even if they be not his progenitors. In fact, we realize, as regards man (though this is not true as regards such animals as the dragon-fly, in which, as we have seen, the mentally acquired is practically non-existent), that the mind of one generation imprints itself on the mind of the next, not racially, but educationally; but, in thinking of this or that adult man, or this or that race of men, we are apt to consider their mental peculiarities as innate and acquired. Especially is this done by men of learning, historians, anthropologists, psychologists, philosophers and the like. It is not realized by them that *man's real mental evolution has lain in the evolution of his power of acquiring mental traits*, and that not in a single other inborn peculiarity does he mentally transcend lower animals, and, therefore, that one adult individual or race must differ from another individual or race wholly in the traits that are acquired, *and in the power of acquiring them*. For example, no man or race is born with greater musical, artistic or mathematical powers than any other man or race, but merely with greater powers of acquiring them; for, in the absence of appropriate stimulation (*i. e.*, experience, education), they do not develop even in the most 'gifted.' It seems probable, moreover, that powers of acquiring these and other particular faculties have not been separately and especially evolved by Natural Selection, but, on the contrary, that they are but particular manifestations of the general power of acquiring mental traits, which is what has been evolved by Natural Selection.* Thus there appears to be no more reason for supposing that the mathematical faculty has been especially evolved than for supposing that the faculty for understanding the uses of machinery has been evolved; both the one and the other must have been equally useless to the primitive savage.

In lower animals the amount of mental receptivity is closely associated with the size of the brain, the larger brain being the concomitant of greater receptivity, and, as a consequence, of lessened instinct. Associated with this truth is the fact that modern representatives of ancient animals (*e. g.*, ungulates) have much larger brains than their ancestors, denoting the evolution in them of the supremely important faculty of acquiring mental characters. Now, since so little that is mental is inborn in man while so much is acquired, we must conclude that differences in the sizes and shapes of the brains of different races imply not inborn mental differences, but differences in the power of acquiring mental characters, and, therefore, for example, that the native Australian, with his small

* Of course, I do not mean by this that the man who is capable, for instance, of high musical attainments, is also necessarily capable of high mathematical attainments. We know that this is not so. Nevertheless, even as regards these faculties much must depend on the 'bent' given to the individual's mind by circumstances occurring early in life.

brain, differs from the Chinaman or Japanese, with his large brain, not mainly in that which is mentally inborn, but mainly in that he has lesser power of acquiring complex mental characters. If this is true, and there is a mass of evidence proving that it is true, for children of one race reared by another and very different race develop the mental features of their educators, not of their progenitors (*e. g.*, Europeans reared by savages or savages reared by Europeans),* then much of the reasoning of numerous thinkers has been founded on false premises, and is invalid. They have commonly estimated the mental calibre of a race by the intellectual feats performed by it, but plainly these are wrong criteria, since whether these feats be great or small depends almost entirely on the environment, that is, on education. A South Sea Islander, for instance, would, and could, do nothing in his ancestral environment compared to what he would be intellectually capable of were he during early life transferred and trained in the midst of a learned and scientific society.

In discussing this subject one is embarrassed by the wealth of the material that presents itself for criticism. In the lightest, as in the weightiest literature, it is constantly assumed that various racial peculiarities and differences which are manifestly acquired are inborn—that this or that race is inherently brave or resolute, or enterprising, or industrious, or gifted with a genius for colonization or empire, while this or that other race is timid, or irresolute, or indolent, or servile, and so forth. To illustrate my remarks and conclude my essay I may cull a few examples from an enormous field. Dr. Francis Galton says: "The importance to be attached to race is a question that deserves a far larger measure of exact investigation than it receives. We are exceedingly ignorant of the respective ranges of the natural and acquired faculties in different races; and there is too great a tendency among writers to dogmatize wildly about them, some grossly magnifying, others as greatly minimizing their several provinces. It seems, however, possible to answer this question unambiguously, difficult as it is."* But, if I am right, as I think I am, in the foregoing, surely *every* writer has too greatly exalted the importance of the inborn and too much minimized the importance of the acquired factor in man. Does not Dr. Galton himself exalt vastly too much the importance of the inborn factor, as witness the following passage, which, in this respect, is similar to many others in his work:

"The long period of the Dark Ages, under which Europe has lain, is due, I believe, in a very considerable degree, to the celibacy enjoined by religious orders on their votaries. Whenever a man or woman was possessed of a gentle nature that fitted him or her to deeds of charity, to meditation, to literature or to art, the social condition of the time was such that they had no refuge elsewhere than in the bosom of the Church. But the Church chose to preach and exact celibacy. The consequence was that these gentle natures had no continuance, and thus, by a policy so singularly unwise and suicidal that I am hardly able to speak of it without impatience, the Church brutalized the breed of our forefathers. She acted precisely as if she had aimed at selecting the rudest portion of the community to be, alone, the parents of future generations. She practiced the arts which breeders would use, who aimed at creating ferocious, currish and stupid natures. No wonder that club law prevailed for centuries over Europe; the wonder rather is that enough

* Consider, for instance, how different in either case would be the contents of memory and all that arises out of memory.

* 'Hereditary Genius,' preface to edition of 1892, p. xxv.

good remained in the veins of Europeans to enable their race to rise to its present, very moderate, level of natural morality." * Dr. Galton implies that a tendency to charity, meditation or to the cultivation of literature is an inborn and transmissible character, whereas they are, in fact, acquired. A Quaker's child, for example, reared by North American or West African savages shows none of the gentle altruistic nature of his progenitors, and obviously shows no literary tendencies. The child of a bloodthirsty and immoral savage may be made sanctimonious to an even unpleasant degree, as has happened under the influence of missionaries in certain Polynesian islands, where by act of the native legislature flirtation is now a legal offence. The children of aborigines have done exceedingly well, as compared to Europeans, in the Australian government schools. The Church, therefore, may have brutalized society in the Dark Ages, by its influence on the characters acquired by the individuals comprising it; for instance, by inculcating celibacy it may have prevented people who had acquired the best characters from having families, and so passing on their acquired excellencies, like language or even property, to descendants. But since mere chance, not innate tendencies, must have determined in each case the inclination or disinclination towards charity, etc., the Church cannot have selectod any *particular type*, and therefore cannot have caused real evolution or retrogression.

It is, of course, impossible for obvious reasons to prove of a particular person with (for instance) charitable inclinations that in a different environment he would have acquired different inclinations. But what cannot be proved of the individual can be proved of the race, which is but an aggregate of individuals. If my definitions are correct, innate inclinations or tendencies are of the nature of instincts, and these can arise only very slowly under the prolonged action of Natural Selection, and, if they disappear, can do so only equally slowly after cessation of selection. But consider how rapidly a race (*e. g.*, the Japanese) may change its characteristics. Consider, in particular, the enormous change, as expressed in the resultant civilization, which occurs in the character of a race when it changes its religion. Compare the mental characters of the races of Asia Minor and North Africa as they changed successively from Pagan to Christian and from Christian to Mohammedan. Consider how much Pagan, Mohammedan and Christian negroes differ in their mental characters. Consider how closely Mohammedans of all races resemble one another mentally. Consider how indistinguishable mentally are Catholic Teutons from Catholic Celts in Ireland, and how markedly they differ both from the Protestant Teutons and the Protestant Celts of Great Britain. I have, however, dealt somewhat fully with this matter of religion elsewhere,* and my space here is limited. Still I am in hopes that the little I have said proves that any tendency towards charity, etc., is wholly acquired and not inborn.

Again Galton says: "The ablest race of which history bears record is unquestionably the ancient Greek, partly because their masterpieces in the principal departments of intellectual activity are still unsurpassed, and in many respects unequalled, and partly because the population that gave birth to the creators of those masterpieces was very small. Of the various Greek sub-races, that of Attica was the ablest."† He further says: "The average ability of the Athenian race is, on the lowest possible estimate, nearly two grades higher than our own—that is, about as

*Ibid, p. 343, 344.

* 'The Present Evolution of Man,' p. 188–196.

† 'Hereditary Genius,' p. 329.

much as our race is above that of the African Negro. This estimate, which may seem prodigous to some, is confirmed by the quick intelligence and high culture of the Athenian commonalty, before whom literary works were recited and works of art exhibited, of a far more severe character than could possibly be appreciated by the average of our race, the calibre of whose intellect is easily gauged by a glance at the contents of a railway book-stall."* De Quatrefage says: "There can be no real relation between the dimensions of the cranial capacity and social development." * * * "By such an extension the Troglodytes of the Cavern of L'Homme-Mort would be superior to all the races enumerated in the table, including contemporary Parisians."† But Mill wrote: "Of all vulgar modes of escaping from the consideration of the effect of social and moral influences on the mind, the most vulgar is that of attributing the diversities of conduct and character to inherent natural differences;"‡ and Buckle, the historian, who, notwithstanding the deficient knowledge of his time, had a true appreciation of the problem, said: "Whatever, therefore, the moral and intellectual progress of men may be, it resolves itself, not into a progress of natural capacity, but into a progress, if I may say so, of opportunity, that is, an improvement in the circumstances under which that capacity after birth comes into play. Here, then, lies the gist of the whole matter. The progress is one not of internal power, but of external advantage. The child born in a civilized land is not likely as such to be superior to one born among barbarians, and the difference which ensues between the acts of the two children will be caused, so far as we know, solely by the pressure of external circumstances, by which I mean the surrounding opinions, knowledge, associations, in a word, the entire mental atmosphere in which the two children are respectively nurtured."*

* Ibid, p. 330–331.

† 'The Human Species.'

‡ Mill's Principles of Political Economy, Vol. I., p. 390.

Mill and Buckle, though unacquainted with the doctrine of evolution, were surely right. The ancient Greeks and Romans were certainly of extraordinary mental prowess, but it is more than probable that they surpassed our more remote ancestors only because the environment in which they lived was more favorable than the mediæval to the acquirement of fit mental traits; because, in their free, intellectual atmosphere, they were trained to the performance of intellectual feats, which were impossible to the fettered minds of our forefathers, who could hardly achieve greatness, except as priests or warriors, or as painters, sculptors, architects, musicians, or as other laborers in such arts as served the grandeur of the Church or the Throne. The splendor of the Greek and Roman achievements, therefore, does not constitute a proof that the Greeks and Romans were splendidly endowed, but only that the traits which they acquired from their progenitors enabled them to use their endowments splendidly. In judging of the mental capabilities of a people as a whole, as in judging of physical powers, it is safer to take as a test their corporal structures, their bodies and brains, rather than their physical and mental feats, for whether these latter be great or little depends on circumstances which may be favorable or the reverse. Had the Troglodytes received the same mental training as the Greeks it is possible or probable, since their brains were large, that they would have performed feats intellectually as great, but had Aristotle or Plato received the training of the cave-men great feats would have been impossible to them. They would have died

* Buckle's History of Civilization, Vol. I., p. 178.

unknown to fame. Moreover, such feats as were performed by the Greeks would not have been recognized as great among prehistoric peoples, and such intellectual giants, but physical weaklings, of the modern world as Darwin and Spencer would have earned, and in that state of society deserved, the contempt of their fellows.

Mr. Herbert Spencer attributes much of the contents of man's mind to the transmission and accumulation of acquired mental characters. Thus he attributes the altruistic feelings to this cause and anticipates a happy future for many by their continued increase. Mr. B. Kidd, whom I confess I have a little difficulty in taking seriously, on the other hand, attributes these feelings to Natural Selection. He is very severe on Mr. Herbert Spencer and writes: "The confusion of ideas to which the tendencies of the times give rise finds remarkable expression in Mr. Herbert Spencer's writings."* The tendencies of the time seem to have confused Mr. Kidd's own ideas to an even greater extent, and it would have been well had he harkened to Mr. Spencer's warning against thinking in abstract terms.†

As already indicated in this JOURNAL,‡ Natural Selection implies elimination of the unfittest, and Mr. Kidd has failed to record a single death as due to the absence of this feeling in him who perished, and the presence of it in him who survived. Having regard to the foregoing, is it not abundantly evident that the altruistic feelings have not undergone evolution at all in man, neither by the transmission of inborn characters nor that of acquired characters? As I say the child of a philanthropist if reared by West African savages might well be a fiend in cruelty, he certainly would have no philanthropic tendencies as we understand them; the child of a cannibal, properly trained, might well develop into a philanthropist; and surely that which may be entirely lapsed or developed in a single generation cannot properly be regarded as a direct product of evolution. Like patriotism, or devotion to a particular religious system, or a knowledge of language, or of letters, or of the uses of steam, or of the bicycle, the altruistic feelings are purely acquired (and not transmissible), and are not immediate products of evolution, but result indirectly from the evolution of man's mental receptivity, that is, from the evolution of his vast power of acquiring mental characters. Men in various times and places have been *taught* to worship sticks and stones, and to hold in reverence all kinds of absurd beliefs and notions, so also a child—any child—by fit training may be rendered highly altruistic—may be taught to receive and practice altruism, as he may be taught to reverence and practice fetishism; whence it follows, as a logical conclusion, that in every individual the altruistic feelings are purely acquired. It matters not that, in a greater or less degree, they are universal. So is knowledge of language and religion, which, though universal, is as much acquired as is a knowledge of history or of astronomy. If, then, in the ancestry of man, these feelings were ever instinctive, as we may suppose them to be among bees, this instinct, like almost all others, was lapsed long ago, and was replaced by an acquired character.* We need not await, then, the slow evolution of the social millenium by the accumulation of inborn altruistic variations, as Mr. Kidd expects, nor by the accumulation (and transmission) of acquired variations, as Mr. Spencer expects. Were we all agreed

* 'Social Evolution,' p. 158.

† 'The Inadequacy of Natural Selection,' p. 67.

‡ September 11, 1897, p. 371.

*I cannot here pause to discuss the cause of the retrogression of instinct. But I have dealt at length with the cause of the retrogression of physical parts in my book, and that of the retrogression of instinct follows the same law. An outline of the theory was given in SCIENCE of September 3, 1896.

as to the training of our children it would be achievable in the very next generation, for surely, if a generation can be reared to reverence a stick or a stone, an inanimate idol, and this or that grotesque religious system, it can be reared also to love and reverence man.

One paragraph more and I have done. We hear of the evolution of morals or of language or of religion, of the printing press, of the locomotive, of the bicycle, and so forth. In the popular mind, and, I fear, even in the minds of some scientific men, this evolution ranks as a process of the same order as the evolution of a plant or animal. Evolution means unfolding, and, therefore, the word is perhaps correctly applied to the bicycle, etc. But there is this essential difference between a living being and the bicycle: The former is the progeny of a parent; the latter is not. So also the language of to-day is in a figurative sense only the progeny of the language of the former times; the morals of to-day have, in a figurative sense only, descended from those of yesterday. All these things are human inventions, and belong not to human evolution, but to what has been called evolution in the environment. The so-called 'Social Evolution,' of which we have lately heard so much, is therefore a myth from the biological standpoint. As I have said, and as I wish to iterate and reiterate, neither the altruistic feelings in particular, nor morals in general, nor anything of the kind, has undergone evolution in man. What has undergone evolution is his enormous power of acquiring characters, these among others. G. ARCHDALL REID.

SOUTHSEA, ENGLAND.

SOME RECENT OBSERVATIONS ON THE INFLUENCE OF THE THYROID GLAND ON METABOLISM.

IN an article by Professor Chittenden, published in SCIENCE, June 25th, a summary is given of what was then known regarding the influence of the thyroid gland on metabolism. Since that time a valuable contribution to our knowledge has come from Bernhard Schöndorff, published in Pflüger's Archiv für Physiologie (Band 67, p. 395). He finds that, contrary to previously received notions, the feeding of thyroid glands or iodothyrin to an animal does not invariably stimulate proteid metabolism. Further he finds that the loss of weight so often observed under such treatment is due mainly to an increased combustion of the body-fats, and that the increased excretion of nitrogen through the urine observed by Voit and others is not necessarily due to an increased proteid metabolism, but to an increase in the excretion of urea and allied bodies which are known to exist pre-formed in the tissues in considerable quantities.

The investigation was carried out on a dog of 55 pounds weight. It was kept in a suitable cage, and its food so regulated that under ordinary conditions the animal remained at a constant weight and in nitrogenous equilibrium. The thyroids were administered for the most part in the form of dry tablets prepared by Borroughs, Wellcome & Co., of London, but sometimes fresh or dried sheep's thyroids were given either alone or with the tablets. At first the dosage was ten of these tablets administered with the daily food. Within a few hours the animal's weight began to fall, and at the end of twenty-three days it had lost nearly two and a half pounds. During the first eight days the nitrogen also showed a minus balance; that given off in the urine and feces amounted to 32 grams, while the food contained only 31 grams. During the next fifteen days, however, there was a plus balance. Evidently these results point to a largely increased consumption and elimination of non-nitrogenous material, and in the light of previous researches Schöndorff attributes them to an increased combustion

of the fats. But they throw very little light upon the proteid metabolism.

For the succeeding twenty-four days the dosage was raised to twenty tablets a day. The effect was unmistakable. The nitrogen eliminated was 4% in excess of that contained in the food. The loss of weight amounted to 2.25 kilos, or nearly five pounds, and at the close of the period the animal was so thin that its ribs and pelvic bones showed plainly. When, however, the nitrogen loss (in all 30 grams) is multiplied by the figure 30, which Pflüger has shown to represent the ratio between the proteid tissues and their nitrogen content, it is evident that the albuminous waste can account for only three-sevenths of the total loss of weight. The other four-sevenths (in all three pounds) must have come from the fats, which implies an increase of combustion to the extent of 43%. The violent panting of the animal points to the same conclusion; while the loss of nitrogen shows that, just as is the case during prolonged hunger, when the supply of fat has been reduced to a certain limit, the system falls back upon its proteids to meet the demands caused by iodothyrin.

At this point the administration of thyroid tablets was stopped, and contrary to the statements of some observers, that iodothyrin has a considerable after-effect, the nitrogen balance became positive immediately and the body weight increased rapidly.

When the animal had again attained its normal weight, the investigation was repeated. Twenty tablets a day were administered. The animal's weight fell a pound a week. For the first few days the nitrogen in the excreta exceeded that in the food by 8%. But the daily analyses showed that by the twelfth day nitrogen demand and supply were again in equilibrium.

At the end of two months, however, the weight ceased to fall. The tablets were discontinued for a week, and the weight rose one and a half pounds. On administering the tablets again for two weeks the weight fell one and a half pounds, but the nitrogen maintained a steady plus balance.

From these facts Schöndorff concludes that in the case of an animal at a uniform weight and in nitrogenous equilibrium iodothyrin causes an increase of combustion and a consequent loss of weight. So long as the store of fat is above a certain limit proteid metabolism, however, remains unaffected; the temporary minus balance of the body's nitrogen is due to an increased elimination of urea and similar substances which existed pre-formed in the tissues; but when the fats have been reduced below a certain limit the proteids are likewise attacked. Throughout his investigations, however, Schöndorff assigns all the effects produced to the iodothyrin contained in the ingested thyroids. He accepts the prevailing opinion of physiologists, that the iodothyrin isolated by Baumann is the full physiological equivalent of the gland, and at no time during the research was the pure substance administered in place of the glands. Yet experiments by Dr. Edm. Wormser, published in a later number of Pflüger's Archiv (Band 67, p. 505), seem to show that the thyroid itself or an aqueous extract of the gland possesses a physiological activity (at least when fed to animals whose thyroids have been removed) far in excess of that exhibited by pure iodothyrin. Similar results have been obtained by A. Schiff, who has been working at this question simultaneously, though quite independently. (Wiener Klin. Wochenschr. 1897, p. 277.) Schiff, however, states that different preparations of iodothyrin vary considerably in the extent of influence they exert, but he asserts that no preparation shows a physiological activity at all comparable to that of the gland itself. If later researches verify these observations they

will prove that, as Wormser claims, iodothyrin is not the only active body secreted by the thyroid, but that some other substance must act with it in order to perform all the functions of the gland.

Wormser's experiments were carried out upon dogs whose thyroids had been carefully removed. The animals were fed with various preparations made from thyroids as well as such artificial compounds as sodium iodide and iodo-casein, and the influence of these substances, in preventing or lessening the tetanus and other symptoms resulting from the operation, was noted.

The first animal experimented upon was fed with dry thyroids for twenty days after the thyroidectomy, and during this time its condition showed nothing abnormal. On the twenty-first day the dry thyroids were replaced by iodothyrin in such quantity that the iodine content equaled that of the previously administered glands. Two days later the animal was seized by a violent tetanus. The dry thyroids were again administered, and the dog recovered in a few hours. The glands were again replaced by iodothyrin, and the animal died within thirty-six hours. This experiment was repeated three times with iodothyrin prepared from sheep and pigs by both of Baumann's methods, and the results agreed perfectly.

Iodo-casein, an artificial compound, has been found efficacious in reducing the size of a goitre. When this substance was administered to dogs whose thyroids had been removed, the intensity of the tetanus seemed to be reduced, but death nevertheless ensued. Similar experiments were tried with sodium iodide, and with the albuminous material precipitated from a sodium chloride extract of the thyroid gland by acetic acid. These results, however, were entirely negative.

Wormser notes, however, that throughout these investigations he found young animals far more susceptible to the evil effects of thyroidectomy than fully mature or old animals, while the appearance of tetanus and other symptoms was delayed by a milk diet, but hastened by one largely composed of meat.

Finally, in summing up the results of his experiments, Wormser points out that the thyroid itself or an aqueous extract of the gland is far more potent physiologically than any substance yet isolated from the gland or artificially prepared, and that therefore no one substance can account for all the functions of the thyroid.

YANDELL HENDERSON.

THE ENZYMIC FERMENTS IN PLANT PHYSIOLOGY.

FERMENTATION, as a general term, covers many of the most important processes in chemistry. Fermentations are of many particular kinds, each depending more or less distinctly upon some specific ferment agent. This makes it convenient to classify the fermentation processes according to the correlated ferment agents. Thus we have yeast fermentation, bacterial fermentation, enzymic fermentation and the like.

The ferment agents, and, following them, the fermentation processes, may be roughly thrown into three classes: (1) Those belonging to the lower orders of fungi, like yeast. (2) Bacteria, like those present in the 'mother' of vinegar, or in the souring of milk. These two classes are often called organic ferments in distinction from the next. (3) Unorganized, or soluble ferments, or enzyms, like diastase, pepsin and ptyalin. The knowledge of these enzyms is mostly of very recent development, and is still fragmentary and generally unsatisfying. They have been best known as they occur in the animal digestive juices. The students of animal physiology have been used for some years to point out the presence of ptyalin and diastase in saliva, of pepsin and trypsin in the gastric juice, and

of pancreatin, trypsin and diastase in the pancreatic secretions. And in a very hazy sort of way it has been known for a considerable time that the same and similar ferments are active in the physiological processes of plants. In very recent years the sharp press of experiment upon all phases of plant economy has brought to light many facts of almost startling interest. We may reasonably hope to collect observations enough within a few years to make generalization practicable; but up to the present we are doing fairly well to get some detached notions of certain of these enzyms, of their nature and action, and their relation to important vegetation processes.

The certain determination, even qualitatively, of all the enzyms present in any given part of a plant can hardly be safely made in any case; but it is known that various enzyms are present in nearly all the living organs. Each plant—especially among the flowering plants—takes up quantities of food materials, which it circulates, digests, stores, unstores, circulates again, assimilates, breaks down and finally, perhaps, excretes. In all the multifarious processes of digestion and redigestion the enzyms may take prominent part. They are almost always found in connection with special food storages, as in buds, tubers, bulbs and seeds.

Before a healthy deciduous woody plant enters upon its period of rest it stores up a considerable quantity of food with which to begin work again in the spring. These storages are largely of starch, and may be demonstrated by the iodine stain under a lens in the woody tissues of stems, especially near buds, or in the roots. The regions of fruit buds in such plants as apple and plum commonly show remarkable storages of this sort. With returning spring, before the roots start or before the leaves are put out to capture and digest food, these stores of starch and other materials are put in motion once more, and from them the new leaves are built or the early blossoms pushed forth. Theoretically and from experiment we are led to believe that these early redigestive processes are dependent on certain enzymic ferments.

In a quite similar manner those plants which propagate their species by means of tubers or bulbs store quantities of food in such organs which later can be reabsorbed and used to start the young plantlet. The recent remarkable results reported by Johanssen before the Agricultural High School of Copenhagen, and so liberally noticed in the public prints of America, were brought about by the application of ether fumes to secure an early liberation of these stores of food in bulbs and dormant woody plants.

Seeds act in the same way. When perfectly ripe and viable seeds are brought into conditions favorable to germination, the relatively large stores of food which they contain are released for the use of the nascent plant. In this case the activity of diastasic ferments is comparatively well known. Perhaps other enzyms are also present and active. The chief commercial source of diastase, in fact, is malt, that is, grain taken at the height of the germination activities. It has been often observed that seeds do not germinate well if planted immediately after ripening; that a period of rest increases the promptness and vigor of germination; and it has been thought probable that this period of rest is useful in allowing the accumulation of the necessary enzymic ferments.

One of the facts of commonest knowledge is that seeds deteriorate in viability when kept for some time. The period at which all the seeds of a sample lose their power of germination varies from two to twenty years or more, but most garden seeds deteriorate rapidly after they are three years of age. It has seemed probable that this

reduction in viability is due to the diminution in quantity or loss in quality of the enzyms in the seeds. Some very interesting experiments made in the experiment station of the University of Vermont tend to establish this theory, as well as to offer some applications of practical value. Various old seeds were treated with different enzym solutions and were then placed in suitable apparatus for germination. One lot of tomato seeds, twelve years old, soaked for twenty-four hours before germination, gave the following results:

Soaked in water,..........	28 per cent	germinated.
Soaked in trypsin,........	56 "	"
Soaked in Extractum pancreatis..................	36 "	"
Soaked in Enzymol, ...	52 "	"

Another lot of seeds of another variety of tomato, twelve years old, gave these results:

Soaked in water,...........	34 per cent.	germinated.
Soaked in diastase, ...	70 "	"

One of the most remarkable experiments was with another lot of tomato seeds, also twelve years old. The result stood:

Soaked in water,...........	12 per cent.	germinated.
Soaked in pepsin, ...	80 "	"
Soaked in diastase, ...	85 "	"

This shows an increase of 567 per cent. and 608 per cent. respectively in the germination through the action of the enzyms artificially supplied. Other seeds of other species and other enzymic preparations gave similar results.

In view of our present knowledge it seems quite fair to hope that, when we understand better the enzyms and their relation to the processes of vegetable physiology, we shall be able to control to our advantage many of the critical steps in plant development.

CURRENT NOTES ON ANTHROPOLOGY.

THE OLDEST CRANIA FROM CENTRAL MEXICO.

IN his work, 'Anthropologie du Mexique,' published in 1884, Professor Hamy gave the measurements of a number of skulls obtained from sepultures of uncommon depths in various parts of central Mexico. Those at Tlaltelolco were from seven to eight feet below the surface and appeared to date from a remote antiquity. These skulls were all characterized by marked brachycephaly, with indices of 85 and upward.

In the *Bulletin du Museum d' Histoire Naturelle*, 1897, No. 6, the same author reports the measurements of five skulls from very ancient burial sites in the district of Colotlan, State of Jalisco. The cranial capacity is good (male 1485, female 1280), but all five of them were remarkably brachycephalic, the average being above 86, and the highest reaching 92.40!

The modern graves, on the other hand, yield skulls which are distinctly dolichocephalic, and the present native population is of this character. They are the Guicholas, speaking a dialect of Nahuatl. They assert that these older graves are not those of their ancestors, but of another race; and the difference in the art-remains substantiates this tradition. Professor Hamy concludes that all the oldest tribes of central Mexico were broad-skulled, with marked alveolar prognathism.

THE OLD LAND-BRIDGE TO EUROPE.

IN the introduction to my 'American Race' I pointed out the arguments for the existence of a land-bridge from North America to Europe in pleistocene times, across which the ancestors of the American man might have journeyed. Since the publication of that work a number of writers have advocated this hypothesis, as Georges Hervé, Charles Tissot, M. Lapparent, etc. The latest is M. Philippe Salmon, ex-President of the Anthropological Society of Paris.

In a paper in the *Revue Mensuelle* of the Paris School of Anthropology, for September, he undertakes to locate the period of the final disruption of the two continents more accurately than heretofore.

He carefully considers the pleistocene fauna of both areas, compares the states of the earliest arts, and especially lays stress on the time and manner of the disappearance of the reindeer in France, and the sudden change of climate from arctic to temperate conditions which that indicates. The cause of this change was the altered direction of the current of the Gulf Stream owing to subsidence of the land areas. His article entitled 'L'Atlantide et le Renne' will be found highly suggestive.

D. G. BRINTON.

SCIENTIFIC NOTES AND NEWS.

AMERICAN MATHEMATICAL SOCIETY.

THE annual meeting of the American Mathematical Society will be held on Wednesday, December 29th, in Room 301 of the Physics Building of Columbia University, New York City. In accordance with the provisions of the constitution of the Society, the annual election of officers will be held at this meeting, and a presidential address, 'On the Philosophy of Hyperspace,' will be delivered by President Simon Newcomb. The sessions will begin at 10:30 a. m. and 2:30 p. m., and the Council will meet at 2 p. m.

The following is a list of papers thus far entered for presentation at the meeting:

Morning Session.

(1) 'On the differential equations defining the Laplacian distribution of density, pressure and acceleration of gravity in the earth,' PROFESSOR R. S. WOODWARD, Columbia University; (2) 'The theorems of oscillation of Sturm and Klein,' PROFESSOR MAXIME BÔCHER, Harvard University; (3) 'On some points in the theory of functions,' PROFESSOR A. S. CHESSIN, Johns Hopkins University; (4) 'Point transformation in elliptic coördinates of circles having double contact with a conic,' DR. EDGAR ODELL LOVETT, Princeton University,' (5) 'Certain invariants of a plane quadrangle by projective transformation,' DR. EDGAR ODELL LOVETT, Princeton University.

Afternoon Session.

(6) Presidential address: 'The philosophy of hyperspace,' President SIMON NEWCOMB, Washington, D. C.; (7) 'Limits of transitivity of substitution groups,' DR. G. A. MILLER, Chicago, Ill.; (8) Some theorems in n-dimensional space,' MR. C. J. KEYSER, Columbia University; (9) 'The orthogonal group in a Galois field,' DR. L. E. DICKSON, University of California.

The Chicago Section of the Society will hold its second meeting on Thursday and Friday, December 30th and 31st, at Northwestern University, Evanston, Ill. Regular meetings of the Society will be held in New York on February 26th and April 30, 1898. The summer meeting will be held next year at Boston, Mass., in connection with the meeting of the American Association for the Advancement of Science.

The membership of the Society now exceeds 300. The November number of the *Bulletin* (Vol. VII., No. 2) contains, besides the 'Notes' and 'List of New Publications,' an account of the International Congress of Mathematicians held at Zürich last August; a report by the Secretary, Professor James McMahon, of the proceedings of Section A at the Detroit meeting of the American Association for the Advancement of Science; 'Quaternions as Numbers of Four Dimensional Space,' by Professor Arthur S. Hathaway; 'Note on the Invariants of n Points,' by Dr. Edgar Odell Lovett; 'Note on the Fundamental Theorem of Lie's Theory of Continuous Groups,' by Dr. Edgar Odell Lovett; 'A Geometrical Locus Connected with a System of Coaxial Circles,' by Professor Thomas F. Holgate; 'Condition that the Line Common to N—1 Planes in an N Space may Pierce a Given Quadric Surface in the Same Space,' by Dr. Virgil Snyder, and a review of Lamb's *Hydrodynamics* by Professor Ernest W. Brown.

The December number of the *Bulletin* (Vol. VII., No. 3), which has just appeared, contains an account of the October meeting of the Society, by the Secretary; 'Note on Hyperel-

liptic Integrals,' by Professor A. S. Chessin; 'Certain Classes of Point Transformations in the Plane,' by Dr. Edgar Odell Lovett; 'Continuous Groups of Circular Transformations,' by Professor H. B. Newson; a review of Plücker's *Collected Papers*, by Professor Charlotte Angas Scott, and 'Notes' and 'New Publications.'

THE AMERICAN SOCIETY OF NATURALISTS AND AFFILIATED SCIENTIFIC SOCIETIES.

THERE is every indication that there will be an unusually full attendance at the Ithaca meeting beginning on Tuesday of next week. The following is a list, revised to December 21st, of those who have already signified their intention of being present.

New York City and Columbia University: Dr. H. F. Osborn, Dr. E. B. Wilson, Dr. G. S. Huntington, Dr. F. S. Lee, Dr. J. McK. Cattell, Dr. S. J. Meltzer, Dr. L. Farrand, Dr. J. A. Blake, Dr. R. Hunt, Mr. N. R. Harrington, Mr. H. E. Crampton, Jr., Dr. Franz Boas, Mr. C. A. Strong, Mr. S. I. Franz, Professor L. M. Underwood, Mr. Lloyd, Dr. C. L. Bristol, Brother Chrysostom.

Harvard University: Dr. G. H. Parker, Dr. G. W. Fitz, Dr. H. M. Richards, Dr. C. B. Davenport, Dr. C. R. Eastman, Miss Ida H. Hyde, Dr. H. P. Bowditch, Professor Chas. S. Minot, Professor W. T. Porter, Professor Josiah Royce.

Philadelphia and University of Pennsylvania: Dr. E. G. Conklin, Dr. J. M. Macfarlane, Dr. John W. Harshberger, Dr. Adeline F. Schively, Dr. Martha Bunting, Dr. Hobart C. Porter, Miss Caroline Thompson, Dr. A. P. Brubaker, Professor G. S. Fullerton.

New Haven and Yale University: Professor W. H. Brewer, Professor R. H. Chittenden, Dr. W. C. Sturgis, Professor L. B. Mendel, Professor Graham Lusk, Professor Herbert E. Smith, Dr. A. W. Evans, Dr. H. B. Ferris.

Baltimore and Johns Hopkins University: Dr. E. A. Andrews, Dr. Ross Granville Harrison, Dr. F. P. Mall, Mr. Charles W. Green, Dr. W. H. Howell, Dr. M. M. Metcalf, Mrs. Christine L. Franklin, Professor E. H. Griffin, Mr. G. Lefevre.

Brown University: Dr. A. D. Mead, Mr. F. P. Gorham, Miss A. G. Wing, Dr. W. G. Everett, Dr. E. B. Delabarre, Dr. H. C. Bumpus.

Princeton University: Professor A. T. Ormond, Professor H. C. Warren, Professor J. G. Hibben, Professor J. Mark Baldwin, Dr. M. W. Urban, Professor William Libbey, Dr. W. M. Rankin.

Washington: Dr. Frank Baker, Professor D. S. Lamb, Dr. W J McGee, Dr. A. McDonald, Professor Chas. W. Stiles.

University of Chicago: Professor C. O. Whitman, Professor Jacques Loeb.

University of Michigan: Dr. J. P. McMurrich, Dr. F. R. Lillie, Dr. W. P. Lombard, Professor J. E. Reighard.

Smith College: Dr. H. H. Wilder, Dr. W. F. Ganong, Dr. W. C. Smith.

McGill University: Professor D. P. Penhallow, Professor E. W. McBride.

Wellesley College: Professor Clara E. Cummings, Dr. Grace C. Cooley.

Middlebury College and University of Vermont: Pro fessor E. A. Burt, Professor D. Irons.

Williams College: Professor S. F. Clarke, Professor J. I. Peck.

Massachusetts Institute of Technology: Dr. R. P. Bigelow, Dr. Theodore Hough.

Syracuse University: Professor C. W. Hargitt, Dr. G. P. Clark.

Tokyo: Professor K. Mitsukuri.

Amherst College: Dr. G. E. Stone.

Rutgers College: Professor John B. Smith.

Clark University: Dr. C. F. Hodge.

Adelbert College: Dr. F. H. Herrick.

University of Wisconsin: Dr. Joseph Jastrow.

Northwestern University: Dr. William A. Locy.

Rhode Island College: Dr. Geo. W. Field.

Union College: Dr. Chas. S. Prosser.

Bryn Mawr College: Dr. T. H. Morgan.

University of Indiana: Professor C. H. Eigenmann.

Wesleyan University: Dr. C. H. Judd.

Allegheny College: Dr. E. L. Rice.

Dartmouth College: Dr. Wm. Patten.

Missouri Botanical Garden: Professor Wm. Trelease.

GENERAL.

IT has for some time been known that Senator Elkins, the 'boss' of the Republican party organization in West Virginia, has been urging the President to appoint as Fish Commissioner a person named Bowers, from Martinsburg, W. Va. The daily papers now contain the statement that this appointment has been definitely settled. The papers consequently charge the President with intending to break the law, which is explicit in regard to the qualifications for the office. We have recently expressed our opinion as to the value and reasonableness of the law, and have every reason to believe that the President would not wish to have it altered. That he should break the law is incredible

IT is expected that the American Society of Naturalists and the affiliated scientific societies meeting at Ithaca will accept an invitation to

meet next year in New York. It is hoped that the Geological Society, at the approaching Montreal meeting, will also decide to hold its next winter meeting in New York.

THE ninth annual meeting of the American Folk-Lore Society will be held at the Johns Hopkins University, Baltimore, on December 28th and 29th.

THE chair in the section of chemistry of the Paris Academy of Sciences, vacant through the death of M. Schützenberger, has been filled by the election of M. Ditte, professor of chemistry at the Sorbonne.

DR. NANSEN will sail from New York on February 19th, and will return directly to Christiania.

PROFESSOR E. JADERAN has proposed to the Swedish Academy of Sciences that an expedition be sent next summer to Spitzbergen to make preparations for the measurement of a degree of latitude in the polar regions. It is then proposed that Russia should be invited to coöperate in the final measurement of a degree in 1899 and 1900.

WE learn from *Nature* that the French government, through its embassy in London, has presented to Sir Archibald Geikie a handsome vase of Sèvres porcelain in recognition of the services rendered by him to the Geological Survey of France.

ACCORDING to the recently published proceedings of the German Zoological Society it contains 205 members, of whom only one, Professor Leuckhart, of Leipzig, is an honorary member.

MR. V. H. BLACKMAN, Hutchinson Research Student of St. John's College, Cambridge University, and Mr. W. Morley Fletcher, Fellow of Trinity College, have gained the Walsingham Medals for biological research.

A COMMITTEE has drawn up a memorial to be presented to the New York Park Board, suggesting that the services of the late William A. Stiles be commemorated by giving his name to one of the newly projected parks in the city.

THE death is announced of Dr. Anthony Brownless, Chancellor of Melbourne University and founder of the medical school of the University, and a distinguished physician and man of science.

MR. JAMES BATEMAN, the botanist and horticulturist, died at Worthing, England, on November 27th, aged 86 years. He was one of the large group of Englishmen of wealth and leisure to whom science in Great Britain is so greatly indebted. In 1833 he sent the collector Colley to Demerara and Berbice to collect plants, and procured many orchids from Guatemala and elsewhere. In 1837 Mr. Bateman commenced the publication of his work on the 'Orchidaceæ of Mexico and Guatemala,' which he completed in 1843; this book, in atlas folio, comprised the most remarkable series of colored plates which had up to that time appeared, each of the plates costing over £200. His 'Monograph of Odontoglossum' appeared between 1864 and 1870.

DR. VON MARZ has presented to the Munich Academy of Sciences the original spectrometer of Fraunhofer, together with his prisms and his manuscripts. As an acknowledgment of this gift the Academy has conferred its gold medal on Dr. von Marz.

MR. ALFRED HARMSWORTH has loaned *The Windward*, the steamship used by the Jackson-Harmsworth expedition to Franz Josef Land, to Lieutenant Peary for his expedition next year.

A RESOLUTION has been introduced in the House of Representatives appropriating $20,000 for the representation of the United States at the International Fisheries Exposition to be held at Bergen, Norway, from May to September of next year.

THE bill passed by Congress prohibiting pelagic sealing by citizens of the United States contains a provision as follows: Section 9. That the importation into the United States, by any person whatsoever, of fur-seal skins taken in the waters mentioned in this act, whether raw, dressed, dyed or manufactured, is hereby prohibited, and all such articles imported after this act shall take effect shall not be permitted to be exported, but shall be seized and destroyed by the proper officers of the United States.

PROFESSOR S. B. BROWN, of West Virginia University, is preparing for the State Geological

Survey Commission a bibliographical and historical sketch of all the work that has been done for the study of geology, biology and the resources of West Virginia by public and private effort.

AT a meeting of the Board of Managers of the New York Zoological Society, on December 14th, it was announced by Professor Henry F. Osborn, Chairman of the Executive Committee, that subscriptions amounting to $65,000 had so far been received for the zoological gardens in Bronx Park. New subscriptions to the fund include $5,000 subscribed by J. Pierpont Morgan, $2,500 by Tiffany & Co., $2,500 by F. Augustus Schermerhorn, $2,500 by Philip Schuyler, $1,000 by George Crocker, $1,000 by Jacob H. Schiff, and $500 by Eugene G. Blackford. The Society now has 540 members.

A ZOOLOGICAL Society has been established in West Australia with a view of founding a zoological garden at South Perth.

MONEY has been appropriated by the trustees of Amherst College for the purchase of a new telescope to replace the old instrument in use at present, and the bequest of $18,000 for the purchase of a site for a new observatory will be expended as soon as the various plans for a new location have been carefully considered.

THE Iron and Steel Institute of Great Britain will hold its annual meeting at Stockholm in August of next year.

DR. ANNINGSON, Dr. Donald MacAlister and Professor Kanthack will represent Cambridge University at the Madrid International Congress of Hygiene and Demography in April, 1898.

AT the 284th regular meeting of the Biological Society of Washington, on Saturday, December 18th, officers for 1898 were elected, as follows: *President*, L. O. Howard; *Vice-Presidents*, B. E. Fernow, Richard Rathbun, F. V. Coville, Chas. D. Walcott; *Recording Secretary*, Charles Louis Pollard; *Corresponding Secretary*, F. A. Lucas; *Treasurer*, F. H. Knowlton; *Councillors*, W. H. Ashmead, C. W. Stiles, E. L. Greene, F. W. True, M. B. Waite.

AT the statutory annual meeting of the Royal Society of Edinburgh, held on November 22d, the following office-bearers were elected for the ensuing session: *President*, The Right Hon. Lord Kelvin, F.R.S.; *Vice-Presidents*, The Hon. Lord McLaren, F.R.S., the Rev. Professor Flint, Professor McKendrick, M.D., F.R.S., Professor Chrystal, Sir Arthur Mitchell, K.C.B., Sir William Turner, F.R.S.; *General Secretary*, Professor P. E. Tait; *Secretaries to Ordinary Meetings*, Professor Crum Brown, F.R.S.; Mr. John Murray, LL.D.; *Treasurer*, Mr. Philip R. D. Maclagan, F.F.A.; *Curator of Library and Museum*, Mr. Alexander Buchan, M.A., LL.D.

AN International Congress of Balneology will be held in Vienna in March, 1898. Further information regarding the Congress may be obtained from the General Secretary, Dr. Brock, of Berlin.

MR. WRAGGE, the meteorologist, who established and worked the first observatory on Ben Nevis, and who is now Meteorological Observer of Queensland, has arrived on the summit of Mount Kosciuszko, the highest mountain in Australia, for the purpose of establishing an observatory there.

THE bequest of the late Sir William McKinnon to the Royal Society for the purpose of furthering natural and physical science, including geology and astronomy, and for the furtherance of original research and investigation in pathology by prizes and scholarships, which we announced last week, will, it appears, amount to more than $80,000.

The Kansas University Quarterly for October contains two important articles by Professor Williston, one on the 'Range and Distribution of the Mosasaurs, with Remarks on Synonomy,' and the other on a Labyrinthodont from the Kansas Carboniferous. This, as Professor Williston remarks, is of particular interest, for while Professor Marsh had described the footprints of Labyrinthodonts from the Upper Carboniferous the tooth noted came from the Lower Carboniferous, or from an earlier horizon than noted elsewhere.

Appleton's Popular Scientific Monthly for January will contain a translation of the important address given by Professor His, of Leipzig, in memory of his friends Ludwig and Thiersch.

BEGINNING with January, 1898, the *American Geologist* will contain an alphabetical author catalogue of articles relating to the geology of North America. Each month's issue will include titles of articles received up to the 20th of the preceding month. Sheets containing this catalogue will be mailed monthly to libraries or individuals at $1.00 per year, provided a sufficient number of orders are received to cover the expense.

THE London *Times* states that the inaugural general meeting of the Automobile Club of Great Britain took place on December 8th, at the Club premises, 4 Whitehall Court, Mr. Roger W. Wallace being in the chair. The objects for which this institution has been established are described as the encouragement and development of the motor and allied industries in England, and one of its leading characteristics is that it is to be essentially a members' club, conducted quite independently of any personal interests. It aims at affording its members support in the protection and defence of their rights where menaced and at being a social club where they may obtain information and advice on all matters appertaining to motor vehicles. At the meeting yesterday the chairman gave a brief review of the position and policy of the Club, and certain routine business was transacted in connection with its organization and the formal opening of its premises for the use of members. Afterwards there was a display of various types of motor vehicles, which conveyed members and their friends for trial runs along Whitehall Court and the Thames Embankment.

UNIVERSITY AND EDUCATIONAL NEWS.

SIR W. C. MCDONALD, whose gifts to McGill University have already been very generous, has just given an additional two hundred and fifty thousand dollars to the institutution. Fifty thousand dollars of this sum is to be used as an endowment in strengthening the law faculty, and the remaining two hundred thousand dollars is for the scientific departments.

A TRAVELLING fellowship, of the value of $500, has been established at Haverford College, through a gift of some of the alumni.

THE contest over the will of the late William Lampson, bequeathing about $500,000 to Yale University, has been dismissed by the lower courts, but it is said that the case will be carried to the Supreme Court.

THE will of the late Mrs. Julia B. H. James makes the Massachusetts Institute of Technology and the Boston Museum of Arts her residuary legatees.

ON the early morning of December 18th Pardee Hall, the building containing most of the scientific departments of Lafayette College, was destroyed by fire, with the exception of the east wing. The loss on the building is probably covered by insurance, but valuable collections have been lost. The original building was erected at a cost of over $200,000, the gift of Mr. Ario Pardee, and was completely destroyed by fire in 1879.

THE registration in the University of Michigan is reported as follows:

Literary	1,297
Law	723
Medical	431
Engineering	274
Dental	220
Pharmacy	77
Homœopathic	60
Total	3,083

THE registration in the different schools of Columbia University on November 7, 1895, 1896 and 1897, respectively, was 1806, 1796 and 2033, exclusive of students of Barnard College and auditors. The college of Columbia University is small, containing only 312 students, but the graduate and professional schools have about the same number of students as the corresponding schools of Harvard University—namely, 1,762 at Harvard and 1792 at Columbia. The entrance classes in Columbia have decreased this year—582 as against 651 in 1896, the loss being in the Medical and Law Schools.

THE Cornell University Register, of which we have received an advance copy, shows a gain in numbers, the total to date being 1,790 as against 1,763 at this time last year. The University now shows the largest registration ever reached at this point in the academic year, and with the usual growth during the year it will have be-

tween 1,800 and 1,900 students in the spring term. The number of students entering the College of Civil Engineering and the College of Agriculture shows large percentages of increase, and the attendance in the New York State Veterinary College is somewhat increased. 431 degrees were conferred in June, 1897, an increase of 50 over any preceding year.

DR. WALDEMAR LINDGREN, of the U. S. Geological Survey, will deliver a course of lectures on mining and metallurgy at Stanford University, but has not accepted a permanent appointment, as has been announced.

MISS JULIA SNOW, PH.D. (Munich), has been appointed instructor in Botany in the University of Michigan.

DR. W. H. R. RIVERS, of St. John's College, Cambridge University, has been appointed university lecturer in experimental psychology. Mr. W. L. H. Duckworth, of Jesus College, has been recognized as a lecturer in anthropology.

MR. J. W. W. STEPHENS, B.A., M.B., Caius and Gonville, has been elected John Lucas Walker Student in Pathology, Cambridge University, *vice* Mr. L. Cobbett, M.A., M.B., Trinity; and Mr. H. K. Wright, M.D., C.M., McGill University, Montreal, has been awarded an exhibition of the value of £50 from the John Lucas Walker Fund.

DISCUSSION AND CORRESPONDENCE.

THE AGONOID GENUS PERCIS OF SCOPOLI.

THE generic name *Percis* of Scopoli has been universally forgotten, but must be revived, and lest it should be overlooked in the great work of Drs. Jordan and Evermann I would call attention to it now. The genus for which the name was proposed by Scopoli is generally known as *Hippocephalus* of Swainson (1839). It was, however, well defined by Scopoli in 1777, and based on the *Cottus japonicus* of Pallas. The description will be found in Scopoli's 'Introductio ad Historiam Naturalem' (p. 454). The only species mentioned was *Percis japonicus*.

The genus *Percis* is the representative of a sub-family distinguished from the *Agoninæ* by the anterior position of the first dorsal fin and may be called *Percidinæ*. The other genera are *Agonomalus* and *Hypsagonus*.

WASHINGTON, D. C. THEO. GILL.

SCIENTIFIC LITERATURE.

RECENT MATHEMATICAL BOOKS.

Elements of Plane and Spherical Trigonometry. By EDWIN S. CRAWLEY, Assistant Professor of Mathematics in the University of Pennsylvania. Second edition, revised and enlarged. Philadelphia, E. S. Crawley. 8vo. Pp. 178.

In the writing of a text-book on Trigonometry there is now-a-days practically no opportunity for any assertion of individuality. The subject is of small extent, definitely bounded, and crystallized into final shape. There is, indeed, a possibility of trimming the treatment down to the absolutely indispensable part of plane trigonometry, which might then be gone over by a class in ten weeks or even less. But the whole tendency is the other way, and chapters on trigonometric equations, De Moivre's theorem, etc.—in short, a pretty complete discussion of the whole field—are now demanded in a text-book. The teacher must decide for himself how much of the whole material he will cover, and he will do well to bear in mind two facts, or rather two phases of the same fact, viz: (1) that teachers of applied mathematics constantly complain that their students do not bring to them a practical working knowledge of trigonometry; (2) that no student, however gifted or however taught, ever fully understands his elementary mathematics until he has gone through the Calculus.

Professor Crawley's book first appeared in 1890. The present second edition has been revised and enlarged by: (1) the adoption of definitions of the trigonometric functions applicable to angles of any magnitude; (2) the addition of a large number of exercises to illustrate the best methods of trigonometric reduction and analysis; (3) a large increase in the number and variety of the examples; (4) additional theorems on the described circles and Brocard's points; (5) a new chapter on De Moivre's theorem and the hyperbolic functions. A previous knowledge of logarithms is expected of the student, and the book is without tables. The plane trigonometry occupies 119 pages, and

the spherical trigonometry 51 pages. Answers are given at the end of the book, but not in cases where they would detract from the value of the examples.

Numerical Problems in Plane Geometry. By J. G. ESTILL. New York, Longmans, Green & Co. 8vo. Pp. x+144.

Of their own motion or in conformity with the unanimous recommendation of the conference of colleges and preparatory schools held at Columbia University in February, 1896, most of the better colleges have abolished the superannuated entrance requirement of a formal examination in arithmetic, and now prescribe in its stead the ability to solve numerical problems in plane geometry and a knowledge of the metric system and in some cases of logarithms. Mr. Estill's book, which is intended to furnish the requisite exercise in all three subjects, contains 49 pages of problems divided into books corresponding to the usual arrangement of the geometries in more general use. These are followed by 52 pages of recent entrance papers of an unusually large number of colleges, together with individual problems taken from similar papers. A five-place table of logarithms, with explanations and examples, occupies the next 38 pages; and the book concludes with the metric tables of weights and measures, including tables of English and metrical equivalents.

The book is not intended to take the place of other geometries, but to be used with them. The problems seem to be generally well selected. The metric system is used from the start, a favorite habit of the author being to give the data in metric units and to require the results in English measure, or *vice versa.* This is, of course, a necessary exercise within bounds, but, when carried to such an extreme as here, is calculated to give the beginner the idea that the metric system is an abominable contrivance for reckoning in terms of incommensurable numbers. Occasionally, too, the answer to a problem is conditioned on the degree of approximation to which the metric and English equivalents are to be taken, and this may well produce a feeling of uncertainty not quite in harmony with the notion of geometry as an exact science.

Plane and Solid Analytic Geometry. By FREDERICK H. BAILEY and FREDERICK S. WOODS, Assistant Professors of Mathematics in the Massachusetts Institute of Technology. Boston, Ginn & Co. 8vo. Pp. xii+371.

Wholly unlike trigonometry, analytic geometry, even in the highly restricted sense in which the name is employed by the present authors, admits of the widest variety of treatment. To what extent shall modern coordinate systems and modern methods generally be introduced? How shall the conic sections be defined? How shall the general equation of the second degree be exploited? Shall anything be said about projective relations and anharmonic ratios? These and many other questions may be settled in the greatest variety of ways by the author, and whatever his decision may be, he can with skill and care produce a highly satisfactory book.

Professors Bailey and Woods have chosen to exclude the more modern apparatus. They do not employ determinants or projective coordinates, or anharmonic ratios, but confine themselves to the ordinary Cartesian and polar coordinates and the common methods. This plan has its advantages. Beautiful and concise as the modern analytic geometry is, the beginner is perhaps not able to appreciate it at once. He must just become acquainted with a large number of new and fundamental ideas and practice himself long and slowly, before he is really able to grasp the perfect theory at all. If he learns great principles prematurely he is apt to have only a superficial understanding of them. At least this is the opinion held by many teachers.

The authors have covered the usual ground so far as plane geometry is concerned. After elementary chapters on coordinates, loci, the straight line, and transformation of coordinates follows one on the circle. The latter serves as an introduction to the conic sections, which are discussed in the next chapter on the basis of Arbogast's definition. This chapter contains also an innovation, the discussion of the general equation of the second degree with the xy term missing, a step which greatly unifies the following treatment of tangents, normals and polars. The discussion of the complete general equa-

tion occupies the last chapter of the plane geometry.

Pages 272 to 359 are devoted to solid geometry. The usual properties of the plane and line are discussed. The quadric surfaces are studied from the simplest forms of their equations, the treatment including the theory of the tangent, polar, diametral planes, conjugate diameters, circular sections and rectilinear generators. The reasoning throughout is clear and rigorous. Defects in the book are the rather scant treatment of problems in loci and the lack of good general (not numerical) examples. The book seems also disproportionately long, considering that Salmon's Conic Sections contains only 400 pages and that Smith's Conic Sections in 191 pages covers pretty well the same ground in plane geometry as the present work. F. N. COLE.

COLUMBIA UNIVERSITY.

A Handbook for Chemists of Beet-Sugar Houses and Seed-Culture Farms. By GUILFORD L. SPENCER, D.Sc. New York, John Wiley & Sons. 1897. Pp. 475.

The beet-sugar industry, one of the most important industries of Europe, has of recent years attracted considerable attention and gained a hold on the public interest in various sections of the United States.

The painstaking and exhaustive researches into the various phases of successful beet-culture pursued for some time by the United States Department of Agriculture, largely under the able direction of Professor H. W. Wiley, have resulted in making available a vast fund of valuable information bearing on the best conditions of soil, climate, etc., for the growing of sugar-beets.

A practical confirmation of the validity of the conclusions determined by these investigations is to be found in the results obtained by the several beet-sugar factories now in successful operation in California, Nebraska, New York and elsewhere in our States. The combined capacity of these factories is, at the present, estimated to be about four thousand tons of beets, daily.

Under these conditions it was felt to be desirable to have a reliable chemical guide for those entering upon the pursuit of this newly developing branch of American industry.

The Handbook for Beet-Sugar Chemists has been written by Dr. Spencer with the express purpose of meeting this need and demand.

The author, who has been connected with the United States Department of Agriculture for some years, and who has taken an active part in its researches and investigations in beet-culture, has certainly acquitted himself ably of the self-set task.

This volume is modeled closely on the lines of the author's earlier publication, 'Handbook for Sugar Manufacturers,' which is devoted almost exclusively to the cane-sugar industry.

Nearly all of the numerous tables of the earlier work are reproduced in this, and, of course, others are added to meet the requirements of the sujects specifically treated of in these pages.

Directions for sampling and averaging beets are carefully given. The optical and chemical methods of sugar-analysis are concisely and clearly described. Analysis of the beet, the juice, the syrup, of the marsecuites and molasses and the sugars, receive attention in separate chapters, as do also the analysis of boneblack, limestone, coke, etc. Proper stress is laid on the principles upon which beet-selection is based and the methods of seed-testing are fully explained. The author's style is clear and lucid ; the numerous references to authorities, given throughout the book, a valuable feature.

The problem of selecting the most desirable methods from the wealth of material stored in the current technical literature is a difficult one and has been well solved by Dr. Spencer. Care has evidently been given to the proofreading; the misspelling of the name Karcz—which is given as Kracz in both text and index—but serves, as an exception, to prove the rule. The text covers about three hundred pages ; it is followed by more than a hundred pages of 'Blank Forms for Practical Use in Sugar House Work,' and some thirty pages are given to a 'Summary of Yield and Losses.' Then follows the index ; in the writer's opinion it had better be placed immediately after the text, to which it refers. The book is bound in morocco;

paper and typography are very good. The insertion of advertisements, however, in a book of this kind seems, to say the least, in questionable taste.

FERDINAND G. WIECHMANN.

The History of Mankind. By PROFESSOR FRIEDRICH RATZEL. Translated by A. J. BUTLER, M. A. New York, The Macmillan Company. 1897. Vol. II., with maps and illustrations. Pp. 562. Price, $4.00.

This is the second volume of the translation of the second edition of Ratzel's 'Ethnographie,' which, for unknown reasons, the publishers have chosen to miscall 'The History of Mankind.' The first volume has already been noticed in this JOURNAL. (See SCIENCE, October 23, 1896.)

It is a handsome book, printed in clear type on excellent paper, with two maps of the distribution of the African races, ten colored illustrations of ethnographic objects and several hundred engravings in the text. These are not fancy sketches, but real helps to the student, selected from the best works of travellers or taken from authentic objects in museums of ethnography.

Professor Ratzel ranks among the chief living authorities on general ethnography, and there is no work in our tongue which surpasses this in abundance and accuracy of information. It can be recommended to readers and students without hesitation.

The present volume takes up the American Indians and the black races of Africa. The author has seen fit to interpolate between these a description of those whom he calls 'The Arctic Races of the Old World,' to wit, the Chukchis, Samoyeds, Gilyaks, Lapps, etc., usually included in the term 'Ural-Altaic Peoples.' Yet he acknowledges (p. 209) that 'we must not talk of a hyperborean race,' and intimates, what is undoubtedly the fact, that these peoples were not originally Arctic dwellers, but lived in the more genial climes to the south.

The Americans he divides, or rather meant to divide, following the artificial distinction of Waitz, into 'wild' and 'civilized' tribes; but the translator has, instead, made the distinction into 'cultured races' and 'civilized races!'—an error repeated in the table of contents and text. This unreal contrast, however, is less respected by the author in his treatment than in his plan. He recognizes the solidarity of native American culture everywhere. He also speaks positively in favor of the unity and antiquity of the race; and, with not quite so clear a note, of the independence of its culture. Nothing could more fully express a true apprehension of the American question than his words (p. 10), "Rightly understood, the New World has to supply the key to the greatest problems of anthropology and ethnology."

In details he is sufficiently full, and usually they are presented with fairness. For instance, on the mooted question of the Eskimos he decides that they are physically affined to Asian types, but in language and culture are Americans. The former is true chiefly of those in Alaska where admixture of blood may be apprehended.

His discussion of the native religions, both of America and Africa, leaves something to be desired. The time has passed when such terms as 'sun-worship,' 'moon-worship,' 'fetishism,' and the like, satisfy the student of comparative religion. These refer to externals merely and do not reveal the real religious thought. The similarities of Polynesian and American mythologies are dwelt upon (p. 147), but the translator pertinently adds in a note (p. 148) that students of Greek mythology will also 'find parallels in every part.'

It seems a deficiency to treat of totems as 'animal and plant symbols' (p. 131); they were much more than that, and often neither animal nor plant. The opinion he intimates (p. 165) that the 'Toltecs' largely created the culture of Central America is surely wide of the mark, as has been shown recently by Sapper, and his estimate of the social condition of ancient Peru (p. 201) is higher than students now would concede.

The negro races of Africa are treated with much ability. He distinguishes between the light-colored stocks, the Bushmen, Hottentots and Dwarfs of the southern and eastern parts of the continent and the Central Africans. He traces the widespread Bantu nations with precision, and gives cogent reasons for believing

their comparatively recent migration into the greater part of their present territory. The Dwarfs he considers anthropologically connected with the older inhabitants of the land and with the southern light stocks. The maps show, the one the limits of the civilizations of Africa, the other the localization of its numerous stocks. They are carefully drawn and useful.

The publication of the English version of this standard work should stimulate the study of this important branch of science. Though too large for a text-book, as a work of reference it should be in every educational library.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

Bau und Leben unserer Waldbäume (Structure and Life of our Forest Trees). By DR. M. BÜSGEN, Professor at the Forest Academy at Eisenach. Jena, Gustav Fischer. 1897. 8vo. Pp. 230.

This timely book fills a long-felt want and is, we believe, the first and only publication in any language which has ever attempted separately and in extenso and yet concisely to bring together all our knowledge of the structure and physiology of this most important group of plants; R. Hartig's and J. C. Müller's Handbooks coming next to such an attempt. This book deals, as the title indicates, with the arboreal forms of Germany; but as these are typical of all temperate zones, and the discussion is of general laws and does not refer to any particular species, it covers our own needs in this field. It is written, as the preface states, "to facilitate orientation for botanists and foresters and for all those non-professionals who desire to obtain an insight into the life and working of our forests."

From this we should not, however, anticipate that the subject has been treated in that 'popular' method of presentation which is characterized by lack of thoroughness and an attempt to please by selection rather than to instruct fully. On the contrary, the book is written in a thoroughly scientific spirit, with due regard to completeness and to the relative importance of the various parts of the subject, albeit here and there treated somewhat scantily.

The author, formerly professor at the University of Jena, has evidently brought to his task not only a thorough knowledge of the literature on the subject, at least the German and French, to which he closely and copiously refers in all particulars, but has compiled the facts with critical judgment.

Having been accustomed by his position to present the subject to a class of students who are trained to make practical use of the same in their professional pursuits, he has known how to lay most weight on the essentials from that point of view. If we add that the diction is simple and the literary style pleasing, we have given all the points that make a good and useful book. Even the usual deficiency of German books, the absence of a full index, is, in part at least, overcome by a 'register of matters not readily to be found through the table of contents.' How very deficient this register is may be illustrated by one example: Although in the chapter on causes of tree form, under the caption 'The Wind,' frost phenomena of arctic regions are discussed—and nowhere else—the index contains no reference under 'frost,' and certainly the table of contents would hardly lead one to the place. The disposition of the material appears often not very logical and hence an index is so much the more desirable.

Lack of space forbids us to go into a critical review in detail. We may only give an idea of the contents by giving titles of chapters. 'The Winter Aspect of Trees' is the title of the first, followed by 'Causes of Tree Form' as the second chapter. These two chapters could, with the aid of N. J. C. Müller's painstaking—unfortunately much overlooked—work have been profitably enlarged. The chapter on 'Buds' is followed by 75 pages devoted to the body of the tree in six chapters, discussing the 'character and functions of the formative tissues of the tree,' 'the elements of the woody tissue' and 'the bark,' the 'annual ring,' 'structure and weight of wood and heartwood formation.' The 'foliage' and 'the root' have each a large chapter devoted to them.

In the chapter on the 'Water Supply of the Tree' we note a curious misconception of an interesting experiment of Strasburger's, into which the great experimenter himself seems to

have been misled, resulting in the statement that 'the living cells of the wood do not take part in the water conduction.' The absurdity of this conclusion, philosophically apparent, can easily be demonstrated by experiment. While as a rule the unfortunate lack of knowledge of the physiology of trees is everywhere acknowledged, it appears to us that with regard to this most difficult problem the writer allows himself to become over-sanguine when he thinks that Dixon and Joly, and Askenay have solved it, however much they may have done to bring the matter under the scrutiny and explanation of physical laws and physical forces.

A chapter on the 'Derivation and Significance of the Mineral Food Elements in Trees' is followed by one on the 'Transformation and Transmission of Food Materials in the Tree,' and a chapter on 'Something about Flowering, Fruiting and Germination' ends the whole somewhat lamely, the necessity of space limitation working disadvantageously in this chapter.

The professors and students of forestry in this country, which are beginning to be called for by our necessities, will find a most convenient compendium of tree physiology in this handbook.

B. E. FERNOW.

Beiträge zur Kenntniss der Septalnectarien. Von J. SCHNIEWIND-THIES. Jena, G. Fischer. 1897. Mit 12 lithographischen Tafeln. Pp. 87.

As is well known, ovarial nectaries are confined to the Monocotyledons, occurring in the Liliifloreæ and in the Scitamineæ. The authoress has made a comprehensive and thorough investigation of these, as the result of which she distinguishes seven different types of nectaries, the simplest of which occur in those genera which stand lowest in the scale of development. The development of the complex out of simpler types can be followed through a series of forms which show strikingly how the development of the vascular bundle system has gone hand in hand with that of the nectary and how the secreting power of the cells has increased in the more complex forms.

In the simplest cases the secretion of nectar takes place all over the surface of the ovary. Next we find the nectaries confined to lines which correspond to the septa and more or less depressed in clefts and furrows. In the higher types we find the nectaries in the interior of the ovary, always occurring in the septa and discharging their secretions by means of an opening which reaches the surface. These internal nectaries are often of complicated structure and may or may not be accompanied by nectaries located on the surface.

The structure of septal nectaries was investigated in a large number of genera belonging to the Liliaceæ, Amaryllidaceæ, Iridaceæ, Musaceæ, Zingiberaceæ, Cannaceæ, Marantaceæ and Bromeliaceæ.

The behavior of nucleus and cytoplasm in the secreting cells was also investigated. During the development of the ovary the secreting cells gradually become differentiated from the ordinary parenchyma cells; their cytoplasm becomes denser and they are very poor in starch, while the parenchyma cells contain an abundance of it. The nuclei of the secreting cells increase in size and become much richer in chromatin than the nuclei of the parenchyma cells; the number of nucleoli often increases. As soon as the differentiation of the tissues of the ovary is complete the secreting cells give a strong reaction with Fehling's solution. Their nuclei in many cases partially lose their walls and assume various constricted, branched and other irregular shapes. The nucleoli diminish in number, size and staining power, except in certain cases, where the reverse takes place.

During the period of their greatest functional activity the secreting cells use up starch stored in the neighboring parenchyma cells. Their cytoplasm gradually diminishes and often disappears completely. The irregular nuclei become still more irregular and often lose their walls entirely. In most cases the chromatin and nucleoli are more or less completely dissolved, but sometimes the chromatin remains intact. The colored plates illustrating changes in cell-structure are of much value, but leave much to be desired in finer details. Some experiments made by the author seem to show that a diastatic ferment is present in the nectary and its secretions.

The comprehensive and thorough investigations of Frau Schniewind-Thies constitute an

important contribution to our knowledge of the anatomy and physiology of septal nectaries and of nectaries in general. Especial mention should be made of the twelve excellent lithographic plates which illustrate nectaries in position in the flower, cross and longitudinal sections of ovaries and nectaries and the details of cell-structure in the secreting cells.

W. J. V. OSTERHOUT.

UNIVERSITY OF CALIFORNIA.

The Living Substance as Such, and as Organism. By GWENDOLEN FOULKE ANDREWS (MRS. ETHAN ALLEN ANDREWS). Supplement to Journal of Morphology, Vol. XII., No. 2. Boston, Ginn & Company. The Athenæum Press. 1897.

This work is devoted principally to discussing the more general questions of biology in the light of the very interesting facts ascertained by the examination of *living* protoplasm under the highest powers of the microscope—a method that of late has fallen into undeserved disrepute, especially so far as metazoa are concerned. Bütchli's theory of the foam-like structure of protoplasm is adopted and a number of additional observations tending to put it on a firmer foundation are recorded. The term 'Bütchli's structure,' however, is used in a sense that would probably not be subscribed to by this investigator, as designating not the foamy structure of protoplasm in general, but merely the foam whose alveoli are from ½ to 1 micron in diameter, excluding the coarser vacuolations on the one hand and on the other the 'finer foam' discovered within the substance of the partitions between the alveoli. It is to this finer foam that the principal rôle in the activities of the living substance is ascribed. The simpler movements, such as amœboid flowing seem to have for their especial organ the 'structure of Bütchli,' but the modifications of these processes, such as those taking place in the minute filose pseudopodia of many protozoa and the more complex activities of protoplasm in general, depend upon the finer foam. By this means the way is pointed out for a reconciliation of the alveolar and fibrillar theories of the structure of protoplasm. True fibres are actually found in the cell in mitosis, and at other times, but from their activities these are considered to be made up of the finer foam and to be frequently comparable to filose pseudopodia, except that they are formed on the inside of the cell.

With this structure as a basis the more general questions are considered and an interesting point of view arrived at. The important thing everywhere is the 'continuous substance' separating the alveoli. The cell is but a differentiation of this, presided over by a metabolic organ, the nucleus. In the living metazoan cells are constantly seen to be connected by a most changeable host of filose pseudopodia along which visible exchange of material may take place. Metabolism is merely a means for furnishing the 'continuous substance' with the proper internal environment, and the organism an accidental organization of it for the purpose of acting upon the external environment and thus furnishing the proper internal surroundings. Heredity is a provision of the substance for the future essentially similar to, though more complex than, the provision for a future internal environment made in injecting food. Thus the necessity for complex theories of transmission vanishes and the study of the structure and activities of the 'continuous substance' becomes of paramount importance.

Unfortunately, the poor style makes the reading much more difficult than the subject warrants. Facts and theories are mixed, unusual constructions are frequent, and in the purely descriptive parts even ambiguous expressions are encountered. That this lack of clearness is apparently due to careless composition seems to be shown by occasional sentences like the following from page 115: "If by coalescence, the substance as such showed respect to that position in the mass in which it newly found itself, exactly as in each individual it had through all its ceaseless flux respected its relative position; for it must not be forgotten that in these protoplasts the substance as such is ever changing its position in the mass or organism."

System der Bakterien, Handbuch der Morphologie, Entwickelungsgeschichte und Systematik der Bakterien, Band I., Allgemeiner Theil. Von DR. WM. MIGULA, a. o. Professor an der

technischen Hochschule zu Karlsruhe. Jena, Verlag von Gustav Fischer. 1897. Octavo of 368 pages, illustrated by 40 photographic reproductions and one diagram.

The volume before us represents the first section of a work on bacteriology. It opens with an instructive critical review of those investigations that have played so important a part in the development of our knowledge of the subject, especially as concerns morphology, classification, etc., dwelling at some length upon the historic works of Leeuwenhoek, O. F. Müller, Ehrenberg, Dujardin, Perty, Cohn, Nägeli, and DeBary.

The second section contains a discussion of the morphology, structure, modes of development and reproduction, chemical constitution, and metabolic activities of bacteria; while the third section is devoted to brief considerations of certain specific biological functions of bacteria—such, for instance, as their relation to culture media, their chromogenic functions, their specific properties of fermentation, anærobiosis, phosphorescence, and their relation to light and to temperature.

It is an excellent presentation of these phases of the subject, especially the section relating to the finer structural details of bacteria. Indeed, this portion of the work is particularly elaborate, the subject being treated with much more detail than is usual. In this respect it may serve to satisfy the demands so frequently made by the botanists for more attention on the part of bacteriologists to the morphological side of bacteriology. We must confess ourselves, however, to be of the number who not only find greater entertainment and instruction from the study of the biological functions of bacteria, but who also believe this to be much the more important line along which to develop the work.

This volume contains no reference to the relation of bacteria to the more highly-organized beings, and comparatively little upon their important rôle in the great processes of nature—points that will doubtless receive due attention in the forthcoming second volume of the work.

The literary references are full and are conveniently grouped at the end of each chapter in alphabetical order.

A. C. ABBOTT.

SOCIETIES AND ACADEMIES.

THE 97TH REGULAR MEETING OF THE CHEMICAL SOCIETY OF WASHINGTON, NOVEMBER 11, 1897.

THE first paper of the evening, read by Dr. H. C. Bolton, was entitled 'Hysterical Chemistry,' a term which he applied to the preposterous theories and claims of a certain small group of writers on chemistry who call themselves Monists. They advocate unity of matter and reject identity, replacing the latter by analogies. He gave examples of their method of reasoning, one instance being the following:

"An atom is a hypothesis,
A hypothesis has no weight, therefore
Atomic weight is a nonentity."

The speaker showed that these writers did little or no experimental work, yet claimed to be revolutionizing chemistry by their publications; also that they deserve no serious consideration.

Mr. Wirt Tassin's paper, entitled 'The Preparation of Crystals,' consisted of a review of the several methods of preparing crystals for the determination of their geometrical and physical constants, the methods being grouped under the following heads:

A. Solution, treating of the preparation of crystals of a substance from its solution in a liquid by evaporating and cooling the solution; by the reaction of soluble compounds, or by chemical changes in general. The general rules to be observed being:

1. The crystallization must proceed as slowly as possible.

2. The solution must be of the least viscosity possible.

3. The crystallizing substance must be present in the solution in the greatest quantity.

4. The crystals desired for measurement must be removed from the solution, preferably when it is at its minimum temperature, and must be quickly and completely dried in order to prevent corrosion or etch figures forming.

B. Sublimation, in which case the crystals may be obtained direct, or a non-volatile compound may be obtained as a result of chemical action between two or more volatile substances, or from a volatile substance and a gas.

C. Fusion, where the crystals are secured by slowly cooling a homogeneous magma, or by a

solution of the substance in a molten magma, and the crystals are formed either with or without pressure.

The last paper of the evening was read by Dr. E. A. de Schweinitz, and was entitled 'A Convenient Dropping Bottle.' This bottle was devised especially to be used by ophthalmologists for the purpose of keeping collyria sterile and free from dust, and at the same time one which was very easy to handle, and from which the solution could be dropped into the eye with almost any desired rapidity. It is a small pear-shaped flask with a long tubular neck at a right angle to the bottle. The end of the neck is drawn out to a moderately fine point and provided with three bends, so that the end of the tube dips downward. The object of these bends is to prevent the dust from entering the bottle. At the same time when they are filled with liquid the rest of the solution is sealed. On the side of the flask opposite the neck is a short open arm, to which a small rubber dropping bulb can be attached to regulate the rapidity with which the liquid is allowed to flow out at the bottom. A little cotton should be placed in this arm to keep out the dust. The dropper is adapted for general microchemical and volumetric work.

Professor Chas. E. Munroe made an exhibit of paraformaldehyde and the lamps used in generating formaldehyde from it. This substance is sold in the form of tablets. Contrary to the general belief, it is comparatively readily soluble in hot water. It makes a convenient laboratory source of formaldehyde. The gas is very readily given off from the tablets at comparatively low temperatures.

Mr. V. K. Chesnut exhibited specimens of *Amanita muscaria*, the fungus which caused the recent death, in Washington, of Count de Vecchj, and the serious poisoning of Dr. Daniel J. Kelly. Colored plates were shown, which showed how the fungus was mistaken for that of the closely related but edible species, *Amanita cæsarea*. Brief remarks were also made about the poisonous constituents characteristic of the two most poisonous Amanitas and their characteristic action on the human system.

V. K. Chesnut,
Secretary.

BIOLOGICAL SOCIETY OF WASHINGTON—283RD MEETING, SATURDAY, DECEMBER 4.

Mr. Lyman J. Briggs presented a paper on 'The Causes of Water Movement in Soils,' showing that the capillary movement of water in soils depends upon the form of the surface of the water contained in the capillary space between two soil grains in contact. The direction and relative magnitude of the pressure of films of several geometrical forms was considered, and the resultant movement of water in soils under such conditions was pointed out.

Mr. Sylvester D. Judd read a paper entitled 'Protective Adaptations of Insects from an Ornithological Point of View.' Such protectively colored insects as grasshoppers, he stated, are eaten in large quantities by practically all land birds that are to any extent insectivorous. The *Geometrid* caterpillars, which so closely simulate twigs, were found in the stomachs of a score of our commonest birds. Vile-smelling or ill-flavored insects, such as many bugs, *Carabid* beetles and *Chrysomellid* beetles, are greedily devoured by the majority of land birds. Numbers of species of insects exhibiting warning coloration and protective mimicry are selected for food by birds. The Kingbird catches the *Erastalis* fly that imitates a honey bee. It also takes honey bees, but in doing so selects only the drones. The author concluded by saying that the interaction between insects and birds does not afford the best example of the greatest efficiency of the protective adaptation of insects.

Dr. Theo. Gill spoke on 'The Distinctive Characters of the Molinæ and Ranzaniinæ,' saying that the family represented by the gigantic sunfish of the Northern Atlantic (*Mola mola*) is also represented by another smaller species, but which is generally regarded as nearly related—the *Ranzania truncata*. These two resemble each other so much superficially that many (including Dr. Günther) have combined them in the same genus. Anatomically, however, they are so widely different that they should be distinguished as subfamily types at least, if not as families. The subfamilies were distinguished as long ago as 1838, by Prince Bonaparte, but the characters partly transposed. The Molinæ have the skeleton mostly cartilaginous and the dorsal and anal fin rays invested in the com-

mon skin, while the Ranzaniinæ (*Orthragoriscini Bon*) have the skeleton 'Sub-osseous' and the rays distinct. The most important of the other characters were detailed.

Dr. C. W. Stiles presented a paper on 'The Honorary Ph. D.'

F. A. LUCAS, *Secretary.*

U. S. NATIONAL MUSEUM,
WASHINGTON, D. C.

THE 268TH REGULAR MEETING OF THE ANTHROPOLOGICAL SOCIETY, TUESDAY, DECEMBER 7, 1897.

THE evening was devoted to a symposium upon Anthropology at the Field Columbian Museum, by Professor Wm. H. Holmes; at the American Museum of Natural History, by Professor Otis T. Mason, and at the Brussels International Exposition, by Dr. Thomas Wilson.

Professor Holmes described briefly the origin and growth of the Field Columbian Museum, of Chicago, and presented a photographic view and ground plan of the building—the Art Building of the World's Fair. The plan was colored to show the arrangements of the departments of the Museum, and especial attention was given to Anthropology. The arrangement of the collections was pointed out and the more interesting and valuable exhibits described.

Professor Otis T. Mason gave a description of the arrangement of the exhibits at the American Museum of Natural History in New York, and dwelt upon the Polynesian collection and the method of its being brought together, stating that each object, as it was obtained, was labeled with its origin, with its surrounding history and every fact that it was possible to find. He noted the difference between the various methods employed by the heads of the several museums, and believed that a diversity of methods was valuable, as it gave an opportunity for the display of each man's idea, and that stress was thus laid on the subject from many points of view.

Dr. Thomas Wilson gave a review of the Brussels International Exposition, of which Professor J. H. Gore and himself were the United States Commissioners. The Exposition was primarily a commercial one and was intended to show, first, what Belgium had to sell, and secondly, what she had to buy. The scientific department was under the direction of a number of scientific gentlemen, of whom Professor Houze was Chairman or Director-in-Chief. The scientific department was located in the great hemi-cycle, which embraced one of the great or main entrances.

Since the United States was only allowed $5,000 by Congress for its exhibit, no part of which could be expended for salaries of the Commissioners or for defraying the freight expenses of private exhibitors from America, the exhibit from this country was necessarily smaller than usual.

The anthropologic exhibit was not large, but was very good. The Belgian division was unusually fine, the prehistoric finds of the caves and grottos being very full and complete.

J. H. MCCORMICK,
Secretary.

TORREY BOTANICAL CLUB, OCTOBER 27, 1897.

THE first paper, by Mr. P. A. Rydberg, entitled 'Botanical Exploration in Montana During the Summer of 1897,' discussed the alpine flora of Montana, adding herbarium specimens and drawings. Mr. Rydberg described a collecting trip made by him and Mr. Ernest A. Bessey to Old Hollowtop, a mountain of 10,000 feet altitude in the Pony or South Boulder Mountains. Their characteristic plants, like those of other alpine regions, are remarkable for their small size and their brightly colored flowers. Most of them are but 2–3 inches high; few exceed 5 inches. The mountain side of Old Hollowtop presents a mixture of golden-yellow, indigo-blue, the richest magenta, the most delicate pink, violet and snowy white, with a carpet of the brightest green for a background. The forage plants of these alpine peaks are chiefly small cespitose clovers, and include but few grasses. Among the trees and shrubs of the alpine peaks, the most remarkable were the five small alpine willows collected, forming a light green mat covering the mountain-side above timber line. The smaller willows of the White Mountains and of the Alps and of Siberia are giants compared with these dwarfs of the Rockies. Four of these

Montana willows, with *Salix rotundifolia* from the island of Unalaska, are the smallest shrubs of *Salicaceæ* in the world. Two of these pygmies are new to science; one of which, growing often only half an inch high, is believed to be the smallest species of willow ever known.

Dr. Britton remarked that Mr. Rydberg's Montana trip of last summer was the first expedition sent out officially by the New York Botanic Garden; to which his collection of alpine plants will return.

Professor Burgess referred to a supposed age of thirty-four years for a dwarf willow of about six inches stem from Alaska, and Dr. Rydberg mentioned twelve years as perhaps the age reached by the dwarfs of his present paper, their stems dying along the rooting base too rapidly to permit great age.

Dr. Rusby spoke of Arctic willows as part of the food of beavers in northern Russia, and of reindeer.

The second paper was by Dr. John K. Small, 'On the Genus Eriogonum North of Mexico,' a genus founded by Michaux upon a single species in 1803, and increased to ninety-five in its fourth monograph, that by Dr. Sereno Watson, in 1870.

In discussing this paper, Dr. Allen contributed an entertaining description of his difficulties in bringing growing specimens of *Eriogonum Alleni* from near White Sulphur Springs to the Botanic Garden here.

Dr. Britton reported that the specimens then secured have done well in cultivation at Bronx Park, and have matured seeds.

Dr. Allen spoke of finding two or three species of *Eriogonum* in the Grand Cañon of the Colorado last summer, and described his descent of the cañon by mule trail, and also his journey to California in search of Characeæ.

Dr. Britton reported two cases of naturalization of escapes from greenhouses; the first that of a creeping form of *Ovalis corniculata*, now becoming a noxious weed at Whitestone, L. I.

The second case is that of a fern, apparently an Asplenium from a temperate habitat.

Other cases of fern naturalization which have been previously reported include that of an Adiantum in Rhode Island, by Mr. Davenport, and a Pteris in a rock-cut near the New York Central Railroad tunnel in our own city, noted by Mr. W. A. Clute.

TIME WASTED.

To what extent are men of science responsible for the credulity which everywhere prevails in reference to all matters relating to scientific discovery or accomplishment? This question is not to be lightly set aside, for the existing condition may well create alarm among all who seriously consider the welfare of science, of scientific men and of the people generally. Several causes have conspired to bring about this condition, two or three of which may be mentioned. To begin with, during the century which is now approaching its end scientific discoveries and their applications have been so numerous and so far reaching as to practically revolutionize conditions of material existence, and they have often been so wonderful in character that it ought not to excite surprise to find intelligent people ready to accept without question announcements of inventions and discoveries of the most improbable and absurd character. Along this line the evil influence of a sensational press is enormous. It was bad enough ten years ago, but it has been greatly magnified by the recent and, on the whole, unfortunate cheapening of processes of illustration to the seductions of which nearly every news-

paper in the land has yielded. To this has been added the newspaper 'syndicate,' by which men who know really nothing of science are employed to furnish sensational articles on scientific discovery, illustrated by sensational pictures, all of which is the more injurious because often founded upon a slender, microscopic tissue of fact. Unfortunately, some men who may be said to inhabit the fringe of genuine scientific activity lend themselves to this sort of thing and are made much of accordingly. Whole pages of this modern journalism are filled with accounts of discoveries that *are going to be made*, for writers of this class are shrewd in taking advantage of the fact that human interest and human memory are now practically restricted to about twenty-four hours in time. The publication of a broadside describing an alleged improvement of the telescope or microscope, in which there is absolutely nothing new that is true or true that is new, adorned with a series of cuts largely imaginary and many of which have no relation to the subject-matter, has served the purpose intended when its author has received his pay from the 'syndicate' and when the syndicate has scored a triumph in what in these days is called 'enterprise.' Even the most conservative among men of science are made to appear as willing purveyors of sensationalism by what ought to be looked upon as an unwarranted and illegitimate use of the results of carefully conducted investigations, often before such results have received final consideration and approval at their own hands.

If *all* impressions made by this false popularization of science were to disappear in twenty-four hours the evil would be greatly lessened, but unfortunately there are many very intelligent and thoughtful people, who ought to constitute the best support of scientific work, upon whom they are more lasting. To such the line separating the genuine accomplishments of honest scholarship from the output of sensationalism, which ought to be clear and sharp, is becoming very nebulous, and there is imminent danger of a revolt against the whole thing. The extent to which credulity has been carried was beautifully illustrated not long ago when a widely known scientific man amused himself and many friends by caricaturing, in the columns of one of our standard scientific journals, some of the phases of modern psycho-physics. So perfectly did the burlesque reflect the form and substance of some recent contributions to that science that it was immediately accepted as serious by the large majority of readers.

This suggestion leads us by easy descent, or ascent, to that large and growing region of pseudo-science, the cultivators of which are, for the most part, themselves honest. For the most part, I say, for it is difficult to believe that all of the persistent advocates of unadulterated nonsense are seriously in earnest. Honest or dishonest, they usually come upon us in much the same way and nearly always find converts in sufficient numbers to enable them to press their fallacious theories upon the public attention. Their appearance is generally sudden and unexpected, and although they have never been heard of in scientific circles before; although they have never done even a small bit of work which might entitle

them to a hearing, they generally begin with some, to them, trifling performance, such as upsetting the law of gravitation or disproving the rotundity of the earth. Such work ought to be harmless, but unfortunately it is not always so. A monthly journal published at the seat of one of our largest universities, not bearing the imprint of the university, however, devotes a large proportion of its space to the exploitation of the belief that the surface of the earth is concave and not convex, presenting in evidence experimental details and results which, if true, would be startling. Such publications as this demand and receive no further attention than the occasional filing away of a copy as a curiosity. Nevertheless, it calls itself a *Scientific Monthly* and 'the greatest scientific paper in America.'

Occasionally books, more dignified in character and appearance but equally unsound in doctrine, are issued, with the imprint of publishers of established reputation, and which seem, therefore, to require more serious consideration. Of this class, is a recent volume bearing the not inappropriate title 'Some Unrecognized Laws of Nature,' the authors being Ignatius Linger and Lewis H. Berens. It is a large, handsomely gotten-up octavo of over five hundred pages and its substitute is 'An Inquiry into the Causes of Physical Phenomena with Special Reference to Gravitation.' The largeness of the subject makes the reader a bit suspicious to start with, and this feeling is considerably enhanced by the first sentence in the preface, which is as follows: "At last, after years of patient plodding in dim regions, where the footprints are few and the pitfalls many, the time has arrived when we are enabled to place before the world of science the first fruits of our exploration." A book with such a beginning means either a great deal or nothing at all, and in the present instance a brief examination of its contents suffices to show that the only message which it brings is the too common one of well-meaning men attempting to explain what they do not themselves understand and to overturn well-established principles of a science of which they appear to be quite ignorant, by the use of arguments and data the soundness of which they are utterly incapable of judging. It is really a rather ostentatious attempt to explain the fundamentals of physical science by men who seem to lack all training in methods of physical research; who show gross ignorance of the latest results of physical investigation, and who are, therefore, totally unfit for the task which they have undertaken. A few citations and examples of their methods and conclusions will furnish sufficient defense for this statement.

They declare that the four great fundamental and universal laws of matter are '*persistence, resistance, reciprocity and equalization*, each one of which,' they say, 'can be seen at work in every single phenomenon within our reach.' Their attack upon the Newtonian law of gravitation consists of the assertion that attraction is not proportional to mass, and this side by side with the equally emphasized assertion that the term 'mass' conveys no distinct idea and that we have really no notion of what it means. This, of course, is mere play, and would be unworthy of comment if it were

not followed by the declaration that the *weight* of a body can be and is changed without changing its mass, some curious experimental evidence being furnished to prove this. The conservation and dissipation of energy are denied and the splendid researches of Kelvin and Joule are overhauled and denounced by critics who declare that "Pressure is 'work' and so is motion." It is declared that Joule could not have obtained the same result for the mechanical equivalent of heat had he used mercury instead of water, and still less had he used friction on copper, iron, glass or wood, even though the 'work' expended were the same. Here the authors seem to be troubled by some sort of a notion of specific heat, and throughout the whole discussion the reasonably well-informed reader cannot fail to be astonished at the unparalleled density of honest ignorance. Their own idea of heat is that it is 'merely a state or quality of bodies, which can be augmented or diminished, and which is due to the states of coercion, *i. e.*, when bodies are prevented from satisfying their natural tendencies.' Their right to speak authoritatively on this subject is further exemplified in the remark that in the case of a falling body "the amount of heat generated will vary as the bodies striking against each other are harder. A quantity of water or mercury falling from a certain height would not generate as much heat as would a like quantity of, say, steel falling from an equal height." Some notions about electricity are reflected in the statement that thin wires offer less resistance than thick wires of the same material, and the further statement, not altogether consistent with this, that the resistance of six pounds of copper would be the same, whether only a yard in length or a mile; also in the statement that the "air between two poles of an electro-magnet can be excited sufficiently to be felt as a viscous fluid when a piece of metal is passed to and fro between the poles."

The extension of some of these unrecognized laws into the domain of astronomy affords the authors ample opportunity for the display of their peculiar logic. In the case of the earth the whole thing is very simple. Its axial motion is due to relative states of excitation of its two hemispheres divided meridianally; the motion of the vanes of a radiometer and of plants turning to the sun is sufficient evidence of this. Its change of seasons is due to a reciprocating motion originating in the relative states of excitation of the two hemispheres, divided equatorially, and its varying distance from the sun is another reciprocating motion due to variations in the aggregate state of excitation of the whole mass. The revolution of the earth about the sun is a simple phenomenon, due to the rolling of one sphere upon the circumference of another. the necessary assumption that the real diameter of the whole earth must be over 500,000 miles being no obstacle to the acceptance of so beautiful a hypothesis.

It is, perhaps, in their review of the Newtonian law of gravitation that the authors reach a maximum in their phenomenal incapacity for an intelligent discussion of the subject. They assume to disprove that law by asserting that according to it the attraction at the equator ought to be greater than

at the poles ; they try to support this assertion by reference to what they call 'another phenomenon, namely, that bodies taken down mines weigh less than when on the surface,' which is not true, as they could have known by even a brief study of gravity before undertaking to upset its accepted principles. They positively declare that two pendulums of different material made to agree in period of vibration at one point on the surface of the earth would *not* agree if carried to others, and, what is more extraordinary, they even suggest this as an *experimentum crucis* by which their theory may be tested. They are blissfully ignorant of the fact that this experiment has been tried many times in many parts of the world and that it has always gone against them, as in the nature of things it must.

It may now well be asked, is time so plenty, is other occupation so scarce and are the columns of SCIENCE so little in demand as to justify so much attention as this book has already received? Perhaps time and space are wasted, but some justification may be found in a few facts, one of which has already been alluded to—the book bears the stamp of a publishing house of the highest character and it has received lengthy and, on the whole, complimentary notice in recognized scientific journals. There is about it something of an air of scholarship calculated to impress and in some degree impose upon those who may be unable to detect its fallacies. There is considerable internal evidence to show that its authors are much more at home with metaphysics than with physics, although this may not be admitted by our brethren of that ilk. Finally, it is perhaps well to make an opportunity for emphasizing the fact that no man has a right to undertake such a discussion as this book pretends to be until he has qualified himself by an exhaustive study of the principles which he proposes to attack. No man has a right to ask the ear of men of science or of an intelligent public on matters relating to science until he has demonstrated his own ability to understand and conduct a scientific investigation, by the presentation of actual, approved work. At first blush it would seem that these men are entitled to pity and sympathy rather than harsh criticism. They richly deserve both, and especially the latter, when their pages abound in the statement that men of science are so restrained by tradition and authority that they do not expect them to receive anything new with favor. This is an old, worn-out plea and utterly inapplicable at the present time. Students of science were never so willing as now to give attention to new theories, however revolutionary they may be, and they do not always insist that they should be immediately supported by facts, provided they emanate from one whose recognized accomplishments are such as to give reasonable assurance that he knows what he is talking about. If the authors of 'Some Unrecognized Laws of Nature' will now spend as much time as they have already spent in making the book in a serious attempt to study and understand some of the recognized elementary principles of physical science, the twentieth century may listen to them, if by that time they have anything to say.

M.

GARDINER GREENE HUBBARD.

In 1883 Gardiner Greene Hubbard and Alexander Graham Bell founded this Journal. It was first published at Cambridge by Moses King, and its first editor was S. H. Scudder. The magazine was designed to be a means of communication between scientific men of America as a bearer of scientific news, an agency for the announcement of scientific discoveries and a forum for scientific discussion. It was not intended as a business enterprise, but it was hoped to establish it on a sure foundation as a gift to American scientific men. The death of Mr. Hubbard was announced in the last week's issue. As one of the original board of directors for the Journal it may be appropriate for us to recount some of his achievements in the interests of scientific affairs.

Mr. Hubbard was born in Boston on the 25th of August, 1822. He came of a scholarly ancestry, his father, Samuel, being an alumnus of Yale, and a Doctor of Laws from Yale, Dartmouth and Harvard, an accomplished lawyer, and a member of the Supreme Court of Massachusetts. The family is English, its first representative in America being William Hubbard, a graduate of Harvard in 1642 and known as an early historian of New England. Mr. Hubbard himself was graduated at Dartmouth in the class of 1841, studied law at Cambridge, and was admitted to the bar in 1843, when he entered the office of Benjamin R. Curtis and remained with the firm until Mr. Curtis was elevated to the Supreme Bench of the United States. Mr. Hubbard continued to practice his profession in Boston for more than twenty years, and subsequently in Washington for five years. The degree of Doctor of Laws was conferred on him by Dartmouth and by Columbian University. His career as a lawyer was eminently distinguished, although it terminated twenty years ago, at which time he was drawn into more active public life.

It is not Mr. Hubbard's legal experience of which we shall speak, but of the rôle which he played in certain public affairs and for which he will long be remembered. In 1860 he was led by the result of a severe illness in one of his children to investigate the possibility of teaching the deaf to speak. At this time there were two systems of instruction for deaf children prevailing in Europe—gesture language and oral speech.

In 1803 Francis Greene, a merchant of Boston who had a deaf child, thus became interested in the education of the deaf and made some study of the oral system. A memorial tablet has just been erected to Greene in Boston. In 1844 Horace Mann went to Europe and made a special study of the subject as it was practiced in Germany, and on his return attempted to introduce the system in America. About the same time the philanthropist Howe, who was the teacher of Laura Bridgeman, became interested in the same subject. An account of the case was published by the Smithsonian Institution. During this epoch the wife of Governor Lippett, of Rhode Island, whose child was deaf, attempted to teach the oral method, and about the same time Mr. Hubbard, whose little daughter had been rendered deaf by severe illness, became interested in oral speech, and by him Miss Rogers was induced to open a school of this character at Chelmsford, near Boston. Mr. Hubbard advertised for pupils for her school and supported it with his own means. The pupils here assembled made rapid progress, when Mr. Hubbard applied to the Legislature for a charter for the school. In the first instance it was refused; the chairman of the committee, himself having a deaf child, was the champion of sign language. Mr. Hubbard was not discouraged; he still pressed the subject on the public and enlisted those who

were especially interested in it by calling attention to the pupils of Miss Rogers' school, one of whom was his own daughter. He again applied to the Legislature for a charter and took the pupils of the Chelmsford school to the State Capitol and gave the committee a demonstration of the utility of the method. At about the same time he also induced Mr. Dudley to permit his child to visit Miss Rogers' school, and she became domiciled for a time at Miss Rogers' residence. In a few weeks Mr. Dudley visited his child, and when he appeared the little girl ran to her father and called him 'Papa.' He found that she was able to converse with him, being able to speak a few words and to understand a few when spoken by Mr. Dudley by interpreting the movements of his lips ; thus Mr. Dudley became a champion of oral speech, and when the subject was again presented to the Legislature he made an eloquent appeal for a charter for the school. At this juncture a gentleman named Clarke offered a sum of money for the endowment of such a school to be located at Northampton ; the benefaction was accepted by the Legislature and the charter was granted. Miss Rogers' school was transferred to Northampton, Mr. Hubbard himself becoming the president of the board of trustees, on which board he continued until his death. Thus was the teaching of speech to deaf children permanently and officially introduced into the United States.

The deaf constitute quite a large class of persons in modern society who have been rescued from a cheerless state by the efforts of philanthropic men. This class of the population had previously been condemned to a state of inactivity and dependence. In future years it will be difficult to appreciate the dreary life of the deaf as it appeared in youth to those who are now passing away with old age. Deprived of the means of intellectual culture, they seemed to be stricken with a paralysis of reason and to wander as useless burdens on society. Instruction in speech has transformed them into helpful independence, so that the deaf may now bear an integral and honorable share in the society of their fellow-men, taking a part in the activities of modern life where the sweet music of speech makes glad the soul. Mr. Hubbard did not invent oral speech, but he became the leader of the men who developed the agencies by which oral speech has become the means of communication among a class of persons who were formerly mutes and who therefore took no part in the arts, industries, institutions and intellectual activities of mankind, while now they may be active, useful and happy members of society.

The student of men as they are engaged in human development may derive a lesson of great interest concerning the interdependence of demotic activities. Arts, industries, institutions, languages and opinions are developed in such a manner that one of these realms cannot be developed without the others. So, for example, a man without institutions is more dangerous than a wolf. In the same manner the investigator as a scientific man engaged in the pursuit of knowledge must depend on the inventor engaged in the application of knowledge, who in turn is dependent on the man of affairs for the utilization of his inventions. To designate this particular class of persons the English language gives us no term. Etymologically the word 'undertaker' is appropriate, but it has been used to designate a director of funerals. The French language has the term *entrepreneur*. Mr. Hubbard was the *entrepreneur* of scientific inventions and discoveries—the man of affairs who pushed them into the service of mankind. He was the *entrepreneur* of oral speech for the deaf, for he introduced it into all of the institutions of America designed to ameliorate the

condition of this class. Men without language are imbecile, as men without institutions are anarchists; but men with language are useful and happy members of the community, as men with institutions are self-respecting citizens.

As a lawyer, business man and benefactor Mr. Hubbard had acquired national reputation, when, in 1876, President Grant appointed him chairman of a special commission to investigate the question of railway mail transportation. The labors of this commission have greatly promoted the intercommunication of the people throughout the Union, for the plans of the commission were adopted by a succession of Postmasters-General and formulated into statutes by members of Congress. The results of his work did not end in national statutes and administrative devices, for he pursued it among telegraph companies.

When Mr. Hubbard was engaged in providing speech for his daughter and then expanding his energies into providing for all the deaf of the nation he naturally became interested in the science of acoustics, and this led him into association with a young student of the science who had already become an inventor. Alexander Graham Bell had so investigated the principles of acoustics that he could invent a telephone. In this instrument Mr. Hubbard evinced a deep interest. It was an instrument to make the inaudible audible, as the microscope was designed to make the invisible visible. At first it was supposed that it might be useful in communicating between different rooms in the same building or between adjoining buildings; but Mr. Hubbard saw in it an instrument of communication for all the governmental departments of a city, all of the business institutions of the city, and all the people of a city. More than this, he conceived that it might be the means of communication from town to town and city to city throughout the country, finally to become a means of international communication. For this purpose Mr. Hubbard devised the business machinery for the introduction of the telephone to the world. He organized a company for this purpose and managed the company by business devices with a great central company and a multitude of local companies by which the telephone business was introduced into all portions of the civilized world. Now a man can be put in communication with his baker through the telephone; in the next minute he may be put in connection with a railroad office or a steamship company; at the next minute with the Governor of his State; at the next minute with some other man elsewhere in the world. To accomplish all this has taken many years of intelligent active labor. Before this we could communicate with the world by lightning light; now we can communicate with the world by lightning sound. The man who devised all this business machinery, set it into operation, and made it all a business success, was Mr. Hubbard.

Mr. Hubbard was not the discoverer of the laws of acoustics which are represented in the telephone; he was not the inventor of the telephone, but he was the *entrepreneur* who distributed the telephone among all men of the civilized world and made it a practical agency for social intercommunication. Having accomplished all these things he retired from business and made his home at Twin Oaks, in Washington City.

At the seat of the federal government there are many bureaus that have to deal with the science of geography. First, there is the time-honored bureau known as the Coast Survey, which is charting the coasts of the sea as an aid to the mariner; then there is the Geological Survey, which is making maps of the United States in the interest of mining and manufacturing;

then there is the Weather Bureau, which is making a daily map of the heavens to exhibit the temperature and storms of the land in the interest of commerce and agriculture; then there is a Hydrographic Bureau preparing charts of all the seas in the interests of foreign commerce. In addition to these great geographical bureaus there are many others that are necessarily interested in geography. Thus, the General Post Office must prepare maps of postal routes. Now the little army of men who are engaged in geographical work in Washington organized themselves into a body known as the National Geographic Society. When they were duly organized they cast about for some one who could manage their affairs as its president and who would interest himself in the diffusion broadcast among the people of this geographical knowledge, which all these bureaus were acquiring. The man selected for this purpose was Gardiner Greene Hubbard, who was elected its first president.

The function of the National Geographic Society is the discussion of the principles of geography and the diffusion of geographical knowledge among the people. To carry out this purpose Mr. Hubbard organized a journal called the *National Geographic Magazine*, which has already acquired a good circulation and become an influential publication. Then he organized a system of bulletins designed to discuss the elements of physiography as a compendious library for teachers in the public schools, and finally he organized in the city of Washington a system of public lectures on geography, enlisting not only the members of the Society, but many other able public men in this enterprise. In all of these agencies the working geographers of Washington most heartily cooperated, and the National Geographic Society has within very few years attained an influence and efficiency which is unequalled in America and perhaps in the world. Thus Mr. Hubbard was the *entrepreneur* of geographical knowledge.

Investigation and discovery lead to useful, honorable and glorious careers, but knowledge must result in invention if it becomes useful, and inventions themselves must be applied to public affairs if they are to be a boon to mankind.

Mr. Hubbard died at three o'clock on the 11th of this month, loved by his kindred, beloved by his friends and honored by the world.

---

*ON THE ORIGIN AND AGE OF THE RELIC-BEARING SAND AT TRENTON, N. J.**

THE locality where human antiquities have recently been found near Trenton, New Jersey, is situated about two miles south of the heart of the city. The points where the finds are being made are on a somewhat extensive plain, the principal formation of which is composed of the sand and gravel deposited by the glacial drainage which came down the Delaware during the last glacial epoch. On the east side of the Delaware the plain extends about two miles east of the locality where the finds are made. It also has a considerable development on the west side of the river, and extends many miles up and down the Delaware north and south of the locality in question. From Trenton it also stretches northeast a number of miles along the Assanpink creek. In the vicinity of Trenton this plain has an elevation of 50 to 60 feet. Through it the Delaware has cut a wide valley, the flood-plain of which is now less than ten feet above sea-level. The relation of the flood-plain to the plain above shows that, after the latter was made, the river excavated a valley in it, cutting it down essentially to tide-level. This valley has been cut since the last glacial epoch.

* Paper presented at the summer meeting of the American Association for the Advancement of Science.

The gravel plain to the east and north of the point where the finds are made ends abruptly at the margin of the post-glacial valley, in a bluff about forty feet in height, with a slope which is about as steep as the material of which it is composed will lie.

The relations shown on the New Jersey side of the river are in a general way duplicated on the Pennsylvania side. The gravel of glacial age has a similar disposition, but the border of the valley on that side is not so sharply defined, indicating that the more recent cutting of the stream has been on the east. The steepness of the bluff of gravel at the points concerned is in itself proof of the recency of the excavation on this side.

The surface of the plain is slightly undulatory, though the relief is usually but a few feet. In places erosion has affected it to some slight extent, and in places its surface appears to have been left slightly uneven by the deposition of the material of which it is made. Its surface is also characterized at various points by low mounds and ridges of sand heaped up by the wind. By this means an element of undulatoriness has been added to the surface as originally left by the deposition of the main body of sand and gravel involved.

While the plain consists of sand and gravel, so far as its general constitution is concerned, its surface is in many places coated with a thin layer of sandy loam, which contains occasional pebbles similar to those which make up the body of the gravel beneath. It is not always possible to say to what extent the surface loam represents the last stage of deposition of the glacial sands and gravel; to what extent it represents the surface accumulation of loamy matter brought up from lower levels by the action of biotic agencies, such as worms, ants, burrowing mammals, etc.; or to what extent it represents deposition by marine or estuarine waters which stood over the region after the glacial drainage ceased to flow through this part of the Delaware.

Relations similar to those where the human relics just south of Trenton are found characterize the east side of the Delaware for many miles further south. In this direction materials derived from glacial waters are less readily identified at most points, but the topography and relations of the plain bordering the Delaware are such as to show that it was developed contemporaneously with the plain at Trenton. Even where not made up chiefly of glacial materials, the plain further south, like that at Trenton, is slightly undulatory, and is coated, in places, with dune sand. Such sand is especially likely to be found on the west edge of that part of the plain which lies east of the Delaware, and just east of the line where the plain descends with a bluff face to the flood-plain of the stream. Well-marked dunes sometimes appear in this situation, and dune sand in larger or smaller quantity is so general that its presence along the edge of the plain above the valley may be said to be the rule, rather than the exception, between Trenton and Camden.

The same is true of the tributaries which come down to the Delaware from the east. Although they did not bring down glacial sands and gravels, they brought down sands and gravels of other sorts, partially filling their valleys, which, like the Delaware, have been re-excavated since. On the bluffs of the tributary valleys, as well as along the main stream, dune sand is of frequent occurrence. In the dune sand along these tributaries, relics of early peoples, consisting of chips of argillite, arrow-heads, and half-fashioned tools of various sorts, are frequently found.

Sand is found in similar relations at some points on the Delaware above Trenton. At many points it has been blown up from the

glacial gravel terraces to higher levels, though it rarely takes the forms of distinct dunes. It is frequently three to five feet in depth, facing the bluffs above the glacial plain in irregular patches, or capping their crests.

The trenches in which the human relics near Trenton have recently been found are upon the immediate edge of the plain overlooking the post-glacial valley of the Delaware. Here, as is frequently the case in such situations, the sandy loam over the gravel of glacial age is thicker than farther back from the bluff, but even here it is but three or four feet in thickness, including the black soil. It is in this sand and loam, quite above the materials which are clearly of glacial age, that the human relics are found.

In detail the sections shown in the trenches open in May and July showed a sandy soil affected by organic matter to the depth of six to twelve inches, the lower limit being ill-defined. The soil graded down into sand which was essentially free from organic matter, and which had a thickness of two to three feet. The sand was without apparent stratification. Below it lay the stratified drift, confidently referred to the time of the last ice epoch. It will be seen, therefore, that the relics were found in the structureless sand and loam which overlay the sand and gravel of glacial age.

Besides being essentially structureless, the sand and loam in which the relics were found contained occasional pebbles. Some of them were as large as one's fist, and occasionally one was found of still greater size, though most of them were tiny pebbles. Many of them were so small as to be within the power of wind to transport, while others were so large as to make this mode of transportation impossible.

In the sand there were at some points streaks more highly colored than the portions above or below. These streaks had a position approaching horizontality, but in detail they were exceedingly irregular. Locally they were interrupted, apparently broken; and in other places they faded out altogether. In general they were thin, a trifling fraction of an inch in thickness. They were sometimes so faint as to be traceable with difficulty, while in other places they thickened to a quarter of an inch or more. While these streaks were often distinct, they were not to be mistaken for lines of stratification, with which they clearly had nothing to do. They could not be assumed to be the edges of stratification plains distorted by unequal sinking, for if this were their origin successive streaks in the same vertical section should have corresponded in their irregularities. This was not the fact, for one streak was liable to bend up just where the one a few inches below it bent down, a relation which excluded the idea of unequal settling. Furthermore, they were so irregular that their total length, as seen in the face of a trench, measuring all irregularities, was considerably greater than the length of the section itself.

These reddish streaks, which were thought to carry more pebbles than the other portions of the sand, seemed to be due to one or more of two or three causes. In places they seemed to be due to the concentration of coloring matter, especially iron oxide. In other places they looked rather as if fine reddish silt had accumulated along them through the influence of percolating water. In either case there must have been something in the texture along this irregular surface to occasion the concentration. The surface of which these irregular lines were the outcrops may perhaps once have been the upper surface of the land, subsequently buried by wind-blown dust and sand. Many of the little irregularities of the streaks were such as might be thus explained, though

the abrupt breaks in them must be accounted for in some other way. So far as I could make out, there was nothing except these reddish streaks which could by any possibility be mistaken for structure, and had I not known at the time of my second visit that they had been taken by others for stratification plains, I should not have supposed this interpretation a possible one.

Concerning the age and origin of the sand which contains the relics, no positive affirmation can be made, and it is only fair to say that this statement is made on the basis of a somewhat full knowledge of the surrounding region. So far as its stratigraphic relations are concerned, the relic-bearing sand might represent the last phase of deposition by glacial waters, or it might belong to any later epoch. Its absence of structure does not show that it was not deposited by water, for in the nature of the case it could not now be expected to show structure, whatever its origin. This would be true whether it represents (1) the last phase of deposition by glacial waters, (2) an estuarine deposit of later age, or (3) eolian sand; for the continually renewed perforation of the sand to the depth of several feet by the roots of plants, the continual borings of burrowing mammals, worms and insects, all of which frequently go down to the bottom of the sand overlying the gravel of glacial age, would quite certainly have destroyed all traces of stratification which the sand may once have had. If this were not enough, the freezing and thawing, and the wetting and drying, would have completed the obliteration of any original structure. For this result even a very few centuries would suffice. It cannot be asserted, therefore, that the sand was not once stratified.

On the other hand, the sand in which the relics are found may have been blown to its present position. The fact that the immediate edge of the bluff is slightly higher than the plain farther back lends color to this view, but the rise next to the edge of the bluff is very slight, and the conclusion that it is due, at this particular point, to an accumulation of wind-blown material is not necessitated. The explanation of eolian sand in this position would be easy. While the river was cutting its valley in the plain, the bluffs were bare. The bare face of the bluff was made of loose sand and gravel, and the prevailing westerly winds might well have blown sand from the slope to the top of the bluff above. This is just the situation in which dune sand would be expected to accumulate under such circumstances, is indeed just the situation in which it has accumulated at many other points along the Delaware and its tributaries. It is probably not exaggeration to say that dune sand occurs in greater or less quantity along the Jersey side of the river, more than half the way between Trenton and Camden, and throughout the stretch its favorite position is on the edge of the river bluff. The dune sand along the tributaries to the Delaware between Trenton and Camden occurs in the same relations. The very general presence in the region of wind-blown sand on the crests of valley bluffs leads one to suspect the same origin for sands in similar situations, such as that in which the relics are found, even when they cannot be proved to be eolian. The case is still further strengthened by the fact that human relics are very generally found in the sand which is demonstrably eolian.

In the presence of the stones there is an apparent difficulty in the way of ascribing the sands in question to the wind. If, however, the sands were accumulated by the wind after the occupation of the region by early peoples, the larger stones may have been dropped by men upon the surface at the same time with the argillite chips and half-fashioned implements, while the smaller ones might have been blown in. But we

are not shut up to this conclusion. There are various other ways in which pebbles might be introduced into eolian sand. The burrowing animals and the growth and decay of the roots of trees might introduce relics and stones from the top, if they were left by men on the surface. Relics of modern civilization, bits of coal, pieces of brick, etc., were found in the sand down to a maximum depth of seventeen inches. The uprooting of considerable trees might bring up gravel stones of considerable size from depths of several feet into the surface material. If forest trees were ever upturned by winds in this locality they could not fail to bring up pebbles into the sand above the gravel. The breaks in the streaks already referred to might find explanation in such disturbances. In view of these possibilities the presence of the pebbles in the sand cannot be asserted to prove that it is not of wind origin.* Finally, it is believed that no unqualified conclusion concerning the origin of the relic-bearing sand is warranted. It may be of aqueous origin, dating from the close of the last glacial epoch; it may be of aqueous origin of later age, for sea water probably covered the region at the close of the last glacial epoch or later; and it may be eolian, dating from a time long subsequent to the deposition of the sand and gravel of the plain.

Whatever its origin, it may safely be said that the surface material down to the lowest depth at which the relics have been found has been so disarranged that no affirmation can be made concerning the origin of the pebbles and relics it contains. It is all within the zone of active weathering and surface disturbance. If the finds were fossils, in the usual sense of the term, it is certain that geologists would not feel warranted in attaching much importance to them.

*My co-laborer in New Jersey, Mr. George N. Knapp, visited the locality where the relics are found in June, and reached the conclusion that the sands in question are eolian. No one else has more intimate familiarity with these sands than he.

ROLLIN D. SALISBURY.
UNIVERSITY OF CHICAGO.

SANARELLI'S WORK UPON YELLOW FEVER.

AT the request of the editor of SCIENCE I append a brief *résumé* of Sanarelli's recent papers upon yellow fever.*

The most important study of yellow fever that appeared before Sanarelli's investigations were undertaken was that made in 1888–9 by Dr. Sternberg, whose researches led to an essentially negative result. Upon only one microörganism found by him in the course of his thoroughgoing investigations did any degree of suspicion fall, and the evidence against this germ was summed up by Sternberg as follows:

"Among the facultative anaërobics is one—my Bacillus X—which has been isolated by the culture method in a considerable number of cases and may have been present in all. This bacillus has not been encountered in the comparative experiments made. It is very pathogenic for rabbits when injected into the cavity of the abdomen.

"It is possible that this bacillus is concerned in the etiology of yellow fever, but no satisfactory evidence that this is the case has been obtained by experiments on the lower animals, and it has not been found in such numbers as to warrant the inference that it is the veritable infectious agent.

"All other microörganisms obtained in pure cultures from yellow fever cadavers appear to be excluded, either by having been identified with known species, or by having been found in comparative researches made outside of the area of yellow fever prevalence, or by the fact that they have

*Annales de l'Institut Pasteur, June, September, October, 1897.

been found only in small numbers and in a limited number of cases."

Sternberg has recently called attention* to the close similarity between his description of the 'Bacillus X' mentioned in the above quotation and the description of '*B. icteroides*' given by Sanarelli, and makes out a strong case for the view that the two are identical.

Sanarelli began his work in February, 1896, shortly after his appointment as Director of the Institute of Experimental Hygiene at the University of Montevideo. In 7 out of 12 autopsies made by him upon the bodies of victims of yellow fever there was found a specific bacillus (*B. icteroides*) which he regarded as hitherto undescribed. The reasons assigned for the failure of himself and others to isolate this microbe in all cases of yellow fever are: 1. That *B. icteroides* multiplies in the human body only to a limited extent, the complete and characteristic effects of the disease being produced by only a very small quantity of toxin. 2. That this toxin, whether directly or indirectly, facilitates to a remarkable degree secondary infection of all kinds. These secondary infections with the colon bacillus, streptococcus, staphylococcus, etc., may of themselves be fatal to the patient, and Sanarelli believes that the fatal termination or several cases observed by him is to be explained in this way. 3. That these mixed infections not only lead to the speedy disappearance of the specific microbe, but also frequently end by transforming the organism of the patient into a culture medium for almost all kinds of intestinal bacteria.

The bacteriological complications arising from these facts enhance considerably the technical difficulties of isolating the specific bacillus. Sanarelli did not succeed in finding the germ in the gastro-intestinal contents and is inclined to doubt if it usually occurs there at all; he did, however, discover it in the circulating blood and in some of the important organs of the body, notably in the liver. He refers to the prevailing belief that the infectious material in yellow fever is localized in the stomach and is to be sought for especially in the black vomit, but prefers, for his part, to regard the gastric disturbances as due to the selective action of the toxin, a view similar, it will be remembered, to his interpretation of the intestinal lesions of typhoid fever.

Bacillus icteroides grows readily upon the ordinary nutritive media, fluid and solid. It is described as a rod about 2μ–4μ in length, with rounded ends, often joined in pairs, and staining readily with the ordinary aniline dyes, but decolorized by Gram's method. The colonies upon a gelatin plate resemble in some particulars those of the colon bacillus, but never show any trace of the chestnut color developed in cultures of the latter; so-called pleomorphism of the colonies is, however, marked.

Contrary to what is true of most of the known pathogenic microbes, the growth of *B. icteroides* upon agar is especially characteristic and furnishes a diagnostic test of the first importance. If the cultures are allowed to develop in the incubator at 37° for from 12 to 24 hours, and are then transferred to a temperature of from 20° to 28°, there is produced what Sanarelli regards as a highly characteristic appearance. The growth at the lower temperature forms a sort of halo around the portion of the colony developed in the incubator, and this appearance is so singular that according to Sanarelli a mere superficial inspection suffices to distinguish immediately, and with the naked eye, a colony of *B. icteroides* in the midst of all other bacterial colonies yet described. As the growth goes on, an effect is produced as if a layer of opaque paraffin had been poured over the agar and then impressions made in it with a small circular seal, the imprints of this seal corresponding with

* *Centralbl. f. Bakt.* I. Abth. XXII., Nos. 6 and 7.

the original transparent colonies grown in the incubator. The final aspect of the culture is compared to a miniature archipelago in which the islets would be represented by the colonies first developed, and the surface of the water by the layer subsequently formed at the lower temperature.

Blood-serum and potato proved themselves to be rather unsuitable media for *B. icteroides*. In milk the germ grows readily, but without producing coagulation. The most favorable fluid medium tested by Sanarelli was beef broth containing lactose and calcium carbonate.

The germ is pathogenic for most of the domestic animals. Mice, guinea-pigs and rabbits succumb readily to inoculation with a pure culture. The rabbit is considered as the most favorable subject for experimental inoculation, and possesses notable advantages over the guinea-pig both in susceptibility and in the regularity and constancy of symptoms and death. The dog, however, presents the most instructive instance of close analogy with the disease yellow fever as it manifests itself in man. Both in the symptoms and in the anatomical lesions Sanarelli was able to trace a correspondence at once constant and precise. As is the case in man, the liver and the kidneys are the organs especially attacked; secondary infections with the streptococcus and colon bacillus sometimes occur.

In the second memoir Sanarelli details the results of his experiments with the yellow fever toxin. Cultures of the germ 15–20 days old, made in ordinary peptonized meat broth and filtered through a Pasteur-Chamberland tube, afforded him a potent toxin. The toxin thus prepared, when injected into the bodies of susceptible animals, produced substantially the same symptoms as inoculation with the specific bacillus. In the dog, particularly, inoculation with the germ-free toxin set in motion the same train of specific symptoms and caused the same pathological changes in the tissues. "The toxin of yellow fever is an exceedingly powerful cellular poison comparable solely, in some points, to the diphtheria toxin. Its contact with the tissue elements of the animal organism, especially the higher species, determines, like that of the diphtheria toxin, a violent irritation, followed by retrogressive processes which always end in the necrosis and fatty degeneration of the protoplasm."

Some very interesting experiments bearing on the question of mixed infection are next described. When *B. icteroides* in sown upon culture media on which, respectively, the colon bacillus, streptococcus and proteus have been previously grown, it is found that the growth of the former is distinctly inhibited by the presence of the soluble products of the other microbes. The latter, on the contrary, grow excellently in a medium previously inhabited by *B. icteroides*, and are only slightly incommoded by the presence of the soluble products of one another, the products of the proteus bacillus seeming most injurious to all concerned. A similar result was revealed by a study of the 'vital antagonism' of *B. icteroides* and the microbes concerned in the secondary infections. Both *streptococcus pyog.* and *staphylococcus pyog. au.* speedily gain the upper hand over *B. icteroides*, and a similar, though less marked superiority, is manifested by the colon bacillus. These facts certainly shed much light on the difficulty of demonstrating the presence of the yellow fever germ in the bodies of victims of the disease, and go far to explain the negative result reached by many observers.

In an attempt to account for the important part played by maritime commerce in the diffusion of yellow fever Sanarelli records a curiously significant observation. It was noticed that gelatin plates sown with *B. icteroides* sometimes remained without development, although agar plates sown at the same time evinced abundant growth. But

if a colony of mould made its appearance on the gelatin plate, colonies of *B. icteroides* immediately sprang up around it. After some days the colonies of *B. icteroides* form a sort of constellation around the mould, the most abundant development taking place in the immediate neighborhood of the latter. This observation was experimentally verified with six species of moulds (not named) 'accidentally isolated' in the laboratory, all of which proved themselves, although in different degrees, capable of favoring the revivification and multiplication of the yellow fever germ. To this singular symbiotic relation Sanarelli is inclined to attribute the ready domiciling of the disease on shipboard and its connection with warmth, moisture and darkness, conditions which, by directly favoring the germination of moulds, indirectly favor *B. icteroides*.

In some brief notes upon the resistance of the germ to physical and chemical agents it is stated that, by exposure of broth cultures to 55°, the germ is killed in about twenty minutes, and that it is instantly destroyed by a temperature of 65°. Dry heat at 110°–125° is speedily fatal, and exposure for one hour and ten minutes at 100° also suffices to destroy vitality. Considerable resistance is shown to desiccation, a result of evident practical importance. In sea water the bacillus shows great vitality, surviving in the sterilized brackish water of the La Plata for upwards of ninety days.

Sanarelli's third memoir is devoted to a consideration of immunity and serum therapy. The serum obtained from the bodies of yellow fever victims causes agglutination of *B. icteroides*, although the intensity of the reaction is said to be quite variable. This serum does not exert any protective power in inoculated animals. Serum from a convalescent provoked a tardy agglutination and manifested a slight preventive power.

An attack of yellow fever in man confers some degree of immunity against a second attack, and hence it would seem as if it might be possible in some way to vaccinate animals against the disease. Attempts to produce immunity in the rabbit failed on account of the excessive sensibility of this animal to the yellow fever virus, and the same difficulty prevented the use of the goat and the sheep. The work upon immunization was mainly limited, therefore, to experiments upon the guinea-pig, the dog and the horse. In all these animals immunization is an unusually difficult and laborious task. While it is possible to immunize a guinea-pig against cholera or typhoid fever in from two to three months, it needs six to seven months of assiduous and delicate work to vaccinate this animal against yellow fever. Dogs may be immunized somewhat more readily, but never become tolerant of large doses of toxin. Horses are treated first with small doses (5–10cc.) of a filtered culture of the germ injected subcutaneously, followed with intravenous injections. After two months of treatment with filtered cultures the more potent doses of cultures sterilized by ether may be used; it is not until five to six months after the beginning of the treatment that the first injection of a living culture may be safely hazarded. During this process of immunization many of the animals die and all are profoundly affected.

The serum of animals immunized in this way is endowed with protective and curative properties and can be used with success in animal experiments. A single instance may serve to illustrate the results obtained by this procedure. A horse under treatment for the space of nine months received subcutaneously during this period 29cc. of filtered cultures and 350cc. of cultures sterilized with ether, and intravenously 2640cc. of sterilized cultures, 345cc. of living broth cultures and 19cc. of an agar culture. The serum (0.5cc.) from this

animal, when injected into a guinea-pig 24 hours before inoculation with several times the fatal dose, conferred immunity; 2cc. proved potent enough to save the lives of guinea-pigs when injected 48 hours after inoculation.

Sanarelli's work upon immunization was still in progress when the third memoir was written, and the outcome of his projected experiments in serum-therapy will be awaited with much interest.

EDWIN O. JORDAN.

LUDWIG RÜTIMEYER.

ON the 25th of November, 1895, died at Basle Ludwig Rütimeyer, the last survivor of a long series of Swiss naturalists, the representatives of the classic period of natural science in this country. Now, two years after the death of this distinguished naturalist, his miscellaneous papers appear in a form capable of attracting the attention of the scientific world.* Rütimeyer's numerous publications, which for a long time chiefly adorned the 'Abhandlungen der schweizerischen palæontologischen Gesellschaft' and the 'Denkschriften der schweizerischen naturforschenden Gesellschaft,' could not be reproduced, but the smaller occasional lectures and writings, which, owing to the astonishing universality of Rütimeyer's researches and studies, deal with questions of zoology and anthropology as well as of geology and geography, are here collected in two volumes. It is well known what a high position the leader of European paleontology, von Zittel, has assigned, for example, to Rütimeyer's paper on the geographical and geological distribution of animals. Whoever shall read this and the similar papers made accessible by this edition will be surprised by the perspicacity of the conclusions and the abundance of openings in every direction of natural philosophy, the exceeding originality and the immense knowledge of details which characterized the man, to whom in the last decades, along with Sir Richard Owen, Vertebrate Paleontology in Europe is most indebted. Among the fundamental questions of zoology we find treated the principles of natural history, the boundaries of animal life, the phylogeny of the vertebrate skeleton, the changes in animal life in Switzerland since the presence of man, the modality of progress in the organic world, general considerations on the sectonic structure of Europe, history of glacier studies in Switzerland, three essays on the Bretagne and addresses in the memory of L. Agassiz, Ch. Darwin, P. Merian and B. Studer, who were in intimate relations with Rütimeyer. The first volume is introduced by an autobiographical sketch, which may give to American naturalists an idea of the development, the many suggestions and difficulties of a Swiss who devoted his life to natural philosophy.

RUD. BURCKHARDT.

BASEL, December 1, 1897.

CURRENT NOTES ON PHYSIOGRAPHY.*

THE GLACIAL LAKE AGASSIZ.

As the Monographs by Gilbert and Russell on the extinct Lakes Bonneville and Lahontan are the classics with regard to basins from which former bodies of water have been withdrawn by evaporation, so

* In SCIENCE for December 3d it was implied that the recent report of the Maryland Geological Survey had neglected possible relations with the schools of the State and devoted its physiographic studies to the interests of 'those who may seek a home in Maryland.' This error was due to my eye having caught the heading 'Study of the Pysiographic Features of the State' (p. 40), in which only the immigrant is referred to as taking advantage of the results; while I failed to note, under the heading 'Preparation of Final Reports,' a very explicit mention of their educational significance. "It is most desirable that the youth of Maryland should grow up with a knowledge of the country in which they live, and be

Monograph XXV. on the Glacial Lake Agassiz, by Warren Upham (U. S. Geol. Survey, Washington, 1895) at once takes its place as a standard work regarding one of those remarkable water bodies which for a time flooded an area marginal to the retreating ice sheet. A great fund of detailed description is here added to the reports already published by Upham and others, regarding the Red river plain, outlets, shore lines, deltas, etc. It is important to note that large areas of the plain at its south end and along either side are mainly composed of unstratified till, and that only the medial part of the plain is covered by lacustrine silts. The plain, therefore, should be classified not only under lacustrine plains, but also under plains of till; the latter species being until recent years unmentioned in text-books. An intricate lacustrine history is revealed by the complicated succession of shore lines which varied with gentle epirogenic movements, and by the changes of discharge from the southern outlet to some more northern lines of overflow. Maps and views are liberally provided. As has been the case with many other phases of glacial study, it is remarkable to discover how largely the existing physiographic conditions of certain regions are dominated to-day by processes associated with glacial action. Yet until very lately our physical geographies gave practically no attention to land forms of glacial origin. This neglect cannot long continue in face of so fine a collection of examples as this great monograph contains.

able to interpret intelligently the physical features of the State." If the people of the State desire it, material adapted for purposes of public instruction will be provided in future volumes.

Having for some years believed that our State Surveys lost a valuable opportunity of serving the public good, and of gaining sound public support by their general neglect of relations with the public schools, I am glad now to make explicit correction of my former note on the Maryland Survey in this regard.

VOLCANOES OF NORTH AMERICA.

Following the plan of his volumes on Lakes and Glaciers, Russell has completed a valuable work on the Volcanoes of America, 'a reading lesson for students of geography and geology' (Macmillan, 1897, p. 346, many plates). A third of the book is given to characteristics of volcanoes, presenting an excellent summary of the subject, excepting that 'erosion of volcanoes' is, for a geographical book, too briefly dismissed in four pages, as compared to thirty pages allotted to products of volcanic action. The descriptive chapters on the volcanoes of different districts summarize the results of our Western surveys, where Russell's own observations play no unimportant part, and abstract many accounts not generally accessible, such as those concerning the explosive eruption of Conseguina, the building of Jorullo, the recent explorations of the lofty Mexican cones, and the surveys of the Alaskan islands. The dissected cones and heavy lava beds of the Yellowstone Park are not mentioned. A chapter of theoretical considerations explains the ascent of lavas from their deep sources chiefly as an escape from the pressure of the enclosing crust, and characterizes steam explosions as relatively superficial incidents instead of prime causes of eruption. A final chapter gives the life history of a volcano. The illustrations are numerous and excellent.

LAKES IN HIGH MOUNTAINS.

E. Fugger has an article on *Hochseen* (Mitth. Geogr. Gesell. Vienna, XXXIX., 1896, 638–672), in which he gives especial attention to the small lakes occurring in the Karen (corries, cirques, amphitheatres) of the Salzburg Alps, the 'normal lakes' of high mountains. He discards the explanation by glacial erosion maintained by Böhm and many others, and Richter's modification of this explanation, where drift ob-

struction is called to the aid of simple excavation. After showing that corry lakes are true rock basins and that local deformation cannot account for them, Fugger advances the idea that they lie in funnel-shaped cavities that once led down to subterranean channels opened by solution, but now obstructed; even advocating this explanation in corries of crystalline rocks, and defending it by a rather elaborate physico-chemical argument.

Apart from the general difficulty of believing in the sufficiency of underground solution in resistant rocks, it seems impossible that erosion thus determined could exceed that effected by the active streams that descend the steep slope on the open sides of corries. As the problem is presented by the writers mentioned above and by various others, glacial erosion seems to be the most competent cause for corry lakes.

THE 14000 MALDIVE ISLANDS.

THE rarely visited Maldive archipelago is described in an interesting article by Rosset (Mitth. Geogr. Gesell. Vienna, XXXIX., 1896, 597–637). The islands are all of coral formation, seldom more than two meters above sea level, with much unhealthy swampy surface. They are seldom more than a few miles in diameter. More than a hundred islets may form the circumference of a single atoll, and sometimes the individual islets themselves have a ring-like, atoll form. The seaward submarine slopes are steep; the shores are attacked by heavy surf, and the natives believe that the land area is decreasing. The islands are separated by deep passages through which strong currents run one way or the other according to the monsoon season. Many channels breach the reefs and give access to quiet anchorages in the lagoons. The colors about an atoll vary from the purple waters off shore to the green, shallow water, the white coral strand, the olive brown reef with dark green vegetation, and the bright green lagoon. A description of the people and their history follows.

W. M. DAVIS.

HARVARD UNIVERSITY.

CURRENT NOTES ON ANTHROPOLOGY.

ELEMENTS OF MELANESIAN ART.

AN article of prime value to students of early art and to anthropologists in general is that by Dr. K. Th. Preuss, in the *Zeitschrift für Ethnologie*, 1897, Heft III. and IV., on the artistic designs of the natives of Kaiser Wilhelms Land, New Guinea. The material he had at his command was a collection of over five thousand specimens now in the Museum of Ethnography, Berlin. He considers it practically complete, presenting the world of their art in line and figure. His article is illustrated with 199 figures in the text, yielding ample means for studying the leading motives of these savage artists. The analysis of their favorite forms is traced out with masterly precision, and as one follows the author in his unraveling the strange and intricate figures he copies, no doubt is left of the success of his undertaking.

In some introductory pages he refers to the bearing of such studies on the question of transmission or independent origin, and on the tendency of primitive man to copy from nature and to conventionalize his copies. Several popular impressions are corrected and sounder methods of comparison explained.

THE EXTENSION OF THE ARAWACK STOCK.

THIS stock of South American languages has peculiar interest, as it is that which spread over the West Indian Archipelago and the Bahamas at some remote date; and if any of the native languages of our Gulf States had South American affinities, they should be looked for in the Arawack and not

in the Carib dialects, as the latter never approached nearer than the south of Cuba.

In the *Zeitschrift für Ethnologie* 1897, Heft II., Dr. Paul Ehrenreich contributes new materials to the tongues spoken on Purus river by the Paumari, Ipurina, Araua and Yamamadi tribes, showing that these are branches of this widespread stock. He remarks : "From the islands of the Antilles far south to the sources of the Paraguay and Madeira rivers, one can now follow an almost unbroken line of Arawack dialects, in which, in spite of the great distance of more than thirty degrees of latitude, it is easy to show a complete grammatical identity."

This is another example of the general fact that the extension of accurate research is rapidly diminishing the number of South American linguistic stocks.

THE ALLEGED SUMMERIAN LANGUAGE.

THE Summerians, so-called, inhabited southern Babylonia about 5,000 years B. C. Their northern branch are known as 'Akkads.' Some say that they spoke a tongue allied to the Semitic stock, while other authorities have maintained that the sufficiently abundant remains of this very ancient idiom show marked analogies to the Ural-Altaic tongues. The latest advocate of this opinion is Dr. K. A. Hermann, of Dorpat, who, at the tenth Russian Archæological Congress, urged strongly that the Summerian had the same construction, vocal harmony and phonetics as the Finnish-Ugrian branch of the Ural-Altaic stock.

In his paper, as reported in the *Centralblatt für Anthropologie*, Dr. Hermann fails to note the objections urged by the eminent Ural-Altaic scholar, Dr. Hugo Winkler to the supposed similarities of Summerian to Ugro-Finnic tongues. These objections are so cogent that they must be held conclusive for the negative. The Summerian, if it was not Semitic, which is still possible, may have been Dravidian, or even a very primitive Aryan idiom. Either of these is more likely than the Ural-Altaic hypothesis.

D. G. BRINTON.

UNIVERSITY OF PENNSYLVANIA.

SCIENTIFIC NOTES AND NEWS.

THE WINTER MEETINGS OF THE SCIENTIFIC SOCIETIES.

THE societies meeting at Ithaca as we go to press represent perhaps the most important attempt to bring the sciences into fruitful relations now existing in America. The National Academy of Sciences and the American Association for the Advancement of Science are more important organizations. They have done more for science in the past, and it may be that they will do more in the future. The National Academy, however, at the present time does not exert a great influence. At a recent session there was only one person present in addition to about twenty members, and each of the papers presented was only of interest to two or three of the members. There was not a line regarding this session in the daily papers of the city in which the Academy met, and it was, perhaps, referred to nowhere except in this JOURNAL. The American Association has during the past ten years had at its annual meetings an average attendance of only about four hundred members with a tendency to decrease. These have by no means been exclusively the four hundred most competent men of science in America, and the total work of the Association has been disappointing. We may hope for much from the anniversary meeting at Boston next year, but it must be acknowledged that at present the Association is in a position to need help from scientific men rather than to give help to them.

The associations devoted to a single science meeting during the Christmas holidays—the Mathematical Society, the Geological Society the Chemical Society and the affiliated societies concerned with the biological sciences convening at Ithaca—are doing their work with thoroughness and with fruitful results. We miss a physical society, but otherwise each of the leading sciences is represented by a well or-

ganized association which is contributing its share to scientific advance. The Society of Naturalists and the affiliated associations are, perhaps, of especial interest because they represent an attempt to keep a group of sciences in mutually helpful relations. Each society has its own organization and special work, but men of science in different but related departments are brought into personal contact, so that each may learn to appreciate the work of the others. The programs of the different societies promise that the meetings this winter will be of special interest, and we are sure that this promise will be confirmed by the reports to be published in this JOURNAL.

THE ECLIPSE EXPEDITIONS FROM GREAT BRITAIN.

ACCORDING to the London *Times* a considerable rearrangement has been made of the stations proposed to be occupied by the various British parties setting out to observe the total eclipse of the sun on January 22d. Sir Norman Lockyer will, as before arranged, occupy the most westerly of these stations—at Viziadrug, on the coast of India. The next station towards the east is where the Southern Mahratta Railway crosses the central line of totality near the station of Karad. Here Professor Michie Smith, the government astronomer at Madras, with his party, will take up his position. The Great Indian Peninsular Railway crosses the central line about 100 miles farther east at Jeur. Here Professor K. D. Naegamvala, the curator of the observatory of the Royal College of Science, Poona, with a large party of resident observers, will be encamped. A wide interval separates this station from the next, which will be occupied by a party sent out by the British Astronomical Association. This will consist of Mr. John Evershed, Mr. and Mrs. E. W. Maunder, Captain P. B. Molesworth, R.E., and Mr. C. Thwaites. This party is travelling out by the P. and O. steamer Ballaarat. Their camp will in all likelihood be pitched at Talni, on the line between Amraoti and Nagpur. Near them will be the second of the official parties sent out by the joint committee of the Royal Society and the Royal Astronomical Society, Sir N. Lockyer's party forming the first, and consisting of Captains Hills, R.E., and Mr. Newall. Mr. Newall has already started, and Captain Hills will travel by the P. and O. steamer Oriental. Another 120 miles along the shadow track the third official station will be occupied by Dr. Copeland, Astronomer Royal for Scotland, on the high road between Nagpur and Seoni; whilst the fourth party, consisting of the Astronomer Royal (Mr. W. H. M. Christie) and Professor H. H. Turner, of Oxford, who also travel by the Ballaarat, is expected to be located at Sohagpur, on the line from Jubbulpore to Bilaspore, some 150 miles from Dr. Copeland. Finally, the second party of the British Astronomical Association, which will be under the leadership of the Rev. J. M. Bacon and will go out by the Egypt, is expected to take up its quarters for the eventful day at Buxar, on the Ganges, some 220 miles farther on. With the favorable meteorological conditions which prevail in India in January and this wide distribution of observing forces, it is to be hoped that no such severe disappointment as was felt in Norway and Japan during the eclipse of last year will be experienced on this occasion.

GENERAL.

As we go to press we receive intelligence of the important discovery announced by Professor J. C. Kapteyn, of Gronigen, that the Star Cordoba Zone Catalogue 5^h. 243 has a proper motion of $8''7$ on arc of a great circle. The largest proper motion hitherto known is that of 1830 Groombridge — $7''0$ on arc of a great circle.

AT the session of the Academie des Sciences held at Paris, December 13, 1897, the Cuvier prize of 1,500 francs was awarded to Professor O. C. Marsh, of Yale University. This prize 'is awarded every three years for the most remarkable work either on the Animal Kingdom or on Geology.'

THE post of Government Botanist of Victoria, vacant by the death of Baron von Mueller, has been filled by the appointment of his former assistant, Mr. J. G. Luehman.

A CABLEGRAM reports that the will of Dr. Thomas W. Evans, the opening of which has been awaited with much interest, leaves nearly

his entire estate, estimated at $8,000,000, for the Thomas W. Evans Museum and Institute of Philadelphia. Further details are lacking.

DR. T. PORTER, whose herbarium was reported to have been destroyed by the recent fire in Pardee Hall, Lafayette College, has made the following statement: "The Pennsylvania flora is saved entire and complete. It is the best in existence, and I am greatly relieved. I have labored a lifetime on it. The collection of North America is saved to the extent of a little more than two-thirds; much that appeared utterly destroyed Saturday proves not to be so badly damaged as to be valueless. The offers of my friends in all directions which are coming in on me like a blessed shower will enable me to restore the collection. I am deeply touched by their generous sympathy and aid."

THE Harvard Natural History Society celebrated on December 17th its sixth anniversary. Professor Shaler gave an address on the history of the Society, and William T. Hornaday, of the New York Zoological Society, lectured on the preservation of our native birds. The Society now numbers over seventy members and has recently been organized into sections for the various branches of natural history.

THE sixty-sixth annual meeting of the British Medical Association will be held in Edinburgh from Tuesday, July 26, to Saturday, July 30, 1898. Since the Association met in Edinburgh twenty-three years ago many changes have taken place in the medical institutions of the city, and the Association will next year be able to meet in McEwan Hall, the magnificent new building of the University of Edinburgh.

THE deaths are reported of Dr. Friedr. Wilhelm Snyder, the botanist, at Braunsberg, at the age of 87 years; of Professor Raphael v. Erlanger, the zoologist, at Heidelberg, aged 33 years; of Dr. Wilhelm Joest, the explorer, in Australia; of Mr. Samuel A. Miller, of Cincinnati, the author of numerous contributions to zoology and paleontology, on December 19th, aged 61 years; of Dr. F. C. Schneider, emeritus professor of chemistry in the University of Vienna, aged 84 years, and of Dr. Schrauf, professor of mineralogy in the University of Vienna, aged 60 years.

WE are requested by Professor I. P. Roberts, Director of the College of Agriculture of Cornell University, to call attention to the university extension work in agriculture, provided last year by the Nixon Bill and placed under the direction of the College of Agriculture. The object of the work is the promotion of agricultural knowledge in the State. A reading course class has been organized for the study of some of the fundamental principles which underlie agriculture, and this study may be taken up at the farmers' homes. Those wishing to join the class, now numbering several hundred, will receive, free of cost, printed matter for study which will be followed by questions intended to lead to a discussion of any points not well understood by the pupil.

THE Société des Laboratoires Bourbouze, of Paris, offers scientific courses to workingmen, free of charge, on Sunday from nine to eleven o'clock. Physics and chemistry will be taught in the laboratories, the courses being adjusted to the practical needs of the students.

DECEMBER 5th was the sixth anniversary of Museum Sunday, instituted in Great Britain by the Sunday Society in 1892. About one hundred institutions were opened on that Sunday. The attendance at the British Museum was 458, and at the Natural History Museum 554. These numbers are scarcely as large as might have been expected.

THE United States Civil Service Commission announces that the examination which was scheduled to be held at Washington and elsewhere on January 8th, for the position of Computor in the Nautical Almanac Office, has been postponed to January 10th and 11th, it being found that it will be necessary to give two days for the examination. Very few applications have as yet been received for examination for this position. All persons desiring to compete should write to the Commission at once for application blanks and information.

PROFESSOR GABRIEL LIPPMANN, who was recently awarded the 'Progress' Medal of the Royal Photographic Society for 'Photography in colors by the interference method,' read a

paper on the subject before the Society on the 14th of December.

WE announced recently that the American Forestry Association would hereafter publish a journal devoted to the interests it represents. *Garden and Forest* states that the Association will take *The Forester*, founded and for the past three years edited by Mr. John Gifford, Princeton, N. J. The new office of *The Forester* will be at No. 73 Cochran Building, Washington.

THE Report of the Director of the Field Columbian Museum for 1896–7 reflects much credit upon the Museum staff, showing that a large amount of work has been accomplished by a small force and that good progress has been made in caring for the study series as well as in installing the exhibits. The report contains a number of plates showing the methods of installation in the various departments. The 'monographic installation of North American forest trees' seems extremely good, both from an educational and scientific standpoint. It comprises a branch, flowers, fruits and block of wood from one tree; a photograph of the same tree in summer and winter; a seven-foot section of the trunk, a transverse section; commercial planks and, finally, a map of North America colored to show the distribution of the species. The mammal groups of Mr. Akeley, who is unrivaled in this work, are deserving of special notice, particularly that of the Lesser Koodoo with its striking central figure. The group of Musk oxen contains, so far as we are aware, by far the best series contained in any museum.

Appleton's Popular Science Monthly for January contains an article on the 'Causes and Distribution of Infectious Diseases,' by Surgeon-General George M. Sternberg. The subject is treated historically, and includes a brief outline of the more serious epidemics of the past one hundred years.

WE quote the following editorial note from the December issue of the London *Educational Times:* "Eulogistic notices of the late J. J. Sylvester, Savilian professor at Oxford, whom our readers will remember as a frequent contributor to our columns, have appeared in the mathematical and other journals of America, France, Germany and Belgium. Professor Halsted, writing in SCIENCE (U. S. A.), says: 'When one thinks that Sylvester, William Thomson, Maxwell, Clifford, J. J. Thomson, have all been second wranglers, one asks involuntarily if any senior wranglers, Cayley excepted, have been put on the same parallel with them?' Professor Halsted might have added Whewell and Glaisher to his seconds. But, as to the seniors, what about Paley (to match Whewell), Wollaston, the double seniors Kaye and Alderson, Herschel, Sir George Airy, Main, Stokes, Adams, Todhunter, Tait, Lord Rayleigh, and Cayley aforesaid? However, it must be admitted that there are some heavy weights in the other scale." There is nothing in any American college or university corresponding to the extreme specialization of the mathematical Tripos at Cambridge. Yet a method which secures such extraordinary results should at least be carefully studied.

To the numerous 'Années' recently established in France will now be added *L'Année sociologique*, edited by M. Durkheim, professor of sociology at Bordeaux, and published by M. Felix Alcan, Paris. The volume for 1897 will be issued early next year and will contain original articles by the editor and by Professor Simmel, of Berlin, followed by systematic reviews of the literature. We regret that the attempt will not be made to give a complete bibliography, but perhaps this will be added to later volumes.

THE *Western Medical and Surgical Gazette*, which has just begun publication at Denver, under the charge of professors in the Gross Medical College is, we believe, the two hundred and twenty-sixth monthly medical journal now being published in the United States. This would allow one monthly journal for each 500 physicians in the country, and probably not one-half of them subscribe for any journal. It is not necessary to predict whether mediocrity or progress through survival of the fit will result. It is, however, but fair to state that the new *Gazette* promises better than many of the medical journals that we receive.

PROFESSOR G. SERGI, of the University of

Rome, expounds in the January *Monist* his theory of the origin of Latin and Greek civilization, which he claims was not the creation of the Aryans, who were an inferior stock, but of the Mediterranean race proper; the Aryans merely transformed the *language* of the Mediterranean races. In the same number Major Powell traces 'The Evolution of Religion' in the light of ethnology and the general history of civilization; Dr. Woods Hutchinson holds an impassioned brief for 'Love as a Factor in Evolution,' wherein he shows that love, sympathy, charity, etc., which are generally supposed to be subversive of natural selection in society, are really the prime conditions of evolutionary progress, through their strengthening of the moral fibre and their enhancing of solidarity. The philosophical articles are: (1) 'Causation, Physical and Metaphysical,' by C. Lloyd Morgan; (2) 'The Philosophy of Laughing,' by Dr. Paul Carus; (3) 'On the Philosophical Basis of Christianity in Its Relation to Buddhism,' by Professor Rudolf Eucken. As for the first of these, Professor Morgan seeks the solution of the problem of causation in the separation of the domain of knowledge into two provinces, a physical province and a metaphysical province. The search for transcendental causation in the latter province is as legitimate in its way as the search for scientific causation in the former province. The book reviews of the number embrace philosophy, psychology, biology and comparative religion.

TEN or twelve years ago *The Critic* published a series of 'Authors at Home,' including sketches of Lowell, Whittier, Holmes and other American men of letters. In its issue for the 18th ult. *The Critic* begins a new series of 'Authors at Home,' with a sketch of 'Charles Conrad Abbott, M.D., at Trenton,' by Mr. Ernest Ingersoll, who holds that 'systematists and dissectors' have not appreciated Dr. Abbott's contribution to science, owing to 'its literary form.'

The Contemporary Review.—Why can we not have in America monthly reviews as good as *The Contemporary*, *The Fortnightly* and *The Nineteenth Century?* — for December contains several articles of scientific interest. A well-informed writer who signs himself 'A British Naturalist' discusses the seal question from an American point of view. The article concludes with the paragraph: "Hence, considering that the industry is commercially of no great importance, that the pelagic sealing involves the killing of pregnant females and the starving of their pups, and that the United States can settle the question over the heads of England and Canada, it seems a pity that the argument should be embittered by abuse of the United States. The question has been so simplified that the officials on both sides no doubt see the advisability of a friendly settlement. And it is to be hoped that the British press will give that fair open-minded consideration to the American claims that has marked the irreproachable attitude of the British Foreign Office."

ANOTHER article in the current number of *The Contemporary Review* is a criticism, by Mr. Andrew Lang, of the recently published work on 'The Evolution of the Idea of God,' by Mr. Grant Allen. Mr. Lang maintains, and not without reason, that Mr. Allen's treatment is not strictly scientific in character, but Mr. Lang himself holds that savages got their idea of spirits from converse with real spirits. Whence the conclusion is not unnatural that literature, science and writing for the market do not combine to produce results of value to science.

AT a recent meeting of the Royal Botanical Society, of London, Mr. Sowerby, the Secretary, called attention, as reported in the London *Times*, to some kola plants grown in the gardens, and said that the tree, which was a native of the west coast of Africa between Sierra Leone and the Congo, belonged to the natural order Stericuliacæ. The seeds, several of which were contained in a fleshy fruit, 4 inches to 6 inches long, were the well-known kola nuts of West Africa, where they had been used as far back as it was possible to trace. By eating these seeds people were enabled to endure prolonged labor and exertion without fatigue. It was estimated that kola paste is five times more sustaining than cocoa; it contained over 2 per cent. of pure caffeine, and, compared with tea, coffee and cocoa, the kola preparations were

far more nutritious and did not create biliousness, as did cocoa and coffee, nor nervous excitability, as in the case of tea, so that the problem of "What may we drink?" might probably be solved. A number of these plants were propagated at Kew in 1880 and distributed to Calcutta, Ceylon, Zanzibar, Demerara, Dominica, Sydney, Mauritius, Java, Singapore and Toronto, where the nuts were now produced. It had been reported from Jamaica that if a demand should arise for them the nuts could be shipped to the extent of many tons per year. Notwithstanding its important properties, it is only lately that any great demand has arisen for the production. As a medical agent it is specially valuable as a powerful nerve stimulant. The kola nuts may supply a valuable medicine to the pharmacopœia, as Mr. Sowerby states, but it is doubtful whether the Kew Gardens have done a philanthropic work in extending its use. It is already sold in large quantities, both in Great Britain and America, and while it may itself be no more harmful than coffee, when mixed with from 10 to 25 per cent. of alcohol, as is usually the case, it becomes a powerful and dangerous intoxicant. The fact that it is sold at apothecaries, often to women and children, rather than in saloons does not decrease the harm that it does.

UNIVERSITY AND EDUCATIONAL NEWS.

IN amplification of the note published last week in this JOURNAL regarding the gifts of Mr. W. C. McDonald to McGill University, Montreal, we are informed that the endowment consists in the foundation of an additional chair of chemistry. It will be remembered that Mr. McDonald recently erected a new chemical building at a cost of $240,000. Mr. McDonald has further now given an additional endowment of fifty thousand dollars for the Faculty of Law, to the Deanship of which Faculty, with the chair of Roman Law, Mr. E. P. Walton, of the Scotch bar, was recently appointed. Mr. McDonald has, moreover, supplemented the existing endowments associated with his name by a further gift of $200,000, to provide for any deficiency in income that may result from the fall in the rate of interest on investments.

THE sum of $45,000 has now been collected for a Science Hall for Syracuse University. It is expected that the erection of the building will be begun in the spring.

MRS. GEORGE SMELTZ, of Hampton, Va., has given $5,000 to Richmond College, to be used in the erection of a science building.

A NEW building for the biological laboratory was begun at Adelbert College in October, and will probably be completed in September, 1898. The building is of Gothic design and is to be built of stone, three stories high and basement. The outside dimensions are about 93 by 63 feet. The estimated cost with equipment is $43,000.

WITH the October Convocation the University of Chicago closed its first period of five years of graduate work, during which it conferred the degree of Doctor of Philosophy on seventy-seven candidates, distributed among the several departments as follows: Zoology, 12; Chemistry, 6; History, 6; English, 6; Sociology, 5; Semitic, 5; Political Economy, 4; Germanic, 4; Greek, 3; Romance, 3; Geology, 3; Physiology, 3; Mathematics, 2; Indo-European Comparative Philology, 2; Physics, 2; Anthropology, 2; Philosophy, 1; Botany, 1; Biblical and Patristic Greek, 1; Political Science, 1; Paleontology, 1; Comparative Religion, 1; Old Testament Literature, 1; Systematic Theology, 1; Church History, 1; not represented, Anatomy, Archæology, Astronomy, Latin and Neurology. The student of science may fairly ask whether, when twelve doctorates are conferred in zoology and but three in Latin and Greek combined, this means that there is less demand for teachers of the classics or that a less exacting preparation is required.

WE quoted in a recent issue the statement of the principal of the 'late' Evelyn College to the effect that the College had been closed because Princeton University refused to recognize its work for the higher education of women. A correspondent fully acquainted with the facts writes us: "Evelyn College was closed on account of bad debts, and in the opinion of its own board of trustees should have been closed some time ago. So far from giving the institution the cold shoulder the University authorities allowed

their names and the University name to be freely used. Various professors expended much time and effort on their courses in Evelyn, and continued to do so, though generally failing to receive the small stipend which was promised them. Certain University officers, both faculty and trustees, served on the Evelyn board, but resigned because they could not approve of the way the institution was financially managed. Seeing that Evelyn College was closed only after the patience of everybody in Princeton, from tradesmen to trustees, was tried to the utmost, and the courtesies of the authorities strained to the breaking point, it is necessary that such a misstatement of the facts should be corrected." These facts do not apparently relieve Princeton University from the responsibility of being the only considerable university in the world that does not provide in any way for the higher education of women.

DISCUSSION AND CORRESPONDENCE.

BEHRING SEA CONFERENCES.

To the Editor of Science: I have read with great interest the article on the results of the Behring Sea conferences, published in your number of November 26th (Science, N. S., Vol. VI., p. 781), which puts forward what is, I believe, the view of the 'seal question' held by most naturalists in every country in a clear and temperate manner. I venture to point out to you that more than four years ago I endeavored to place the question in a somewhat similar light before the British public in an article entitled 'A Naturalist's View of the Fur-Seal Question,' published in *The Nineteenth Century* for June, 1893, Vol. XXXIII., p. 1038). I beg leave to add an extract from this article in order to show the conclusions to which I had then arrived: "The absolute prohibition of 'pelagic' sealing which is demanded by the Americans, and which out to be carried out in order to ensure the continued existence of the fur-seals, can only be obtained by mutual arrangement among the parties interested. The fur-seal of Alaska (practically now the only remaining members of the group of fur-seals) should be declared to be, to all intents and purposes, a domestic animal, and its capture absolutely prohibited except in its home on the Pribilof Islands. Looking to the great value of the privilege thus obtained, America might well consent to pay to Great Britain and her colonists some compensation for the loss of the right of 'pelagic' sealing; the amount of this compensation would be fairly based upon the number of fur-seals annually killed upon the Pribilof Islands. The 'royalty' thus levied would no doubt increase the price of seal-skin jackets. But seal-skin jackets are not a necessary luxury, and an additional pound added to their cost would not be of material consequence to the ladies who wear them. As a naturalist, therefore, I think that the fur-seal should be considered in the light of a domestic animal, and that all 'pelagic' sealing should be stopped, while the owners of the sealeries should at the same time pay to the other nations interested a reasonable compensation for the valuable privileges thus obtained."

THE ENCHANTED MESA.

To the Editor of Science: Referring to your postscript to my letter written in response to a communication to Science by Professor Libbey, I take the liberty of saying that, as the gentleman mentioned has *not* stated positively that *he* erected the stone monument on the summit of the Enchanted Mesa, one must reach such a conclusion only by inference. My reasons for not accepting anything short of a statement couched in unmistakable terms are based on what Professor Libbey has already contributed to the literature of the Enchanted Mesa. In the first place (*Princeton Press*, July 31) he says:

"No traces of former inhabitants were found. Further, no altars or traces of prayer sticks were found. * * * Not the slightest trace was found which would enable me to believe that a human foot had *ever before passed* over the top of this famous rock."

Again (*Princeton Press*, August 21) he says:

"For two hours I walked over the surface of the rock. * * * It is a splendid site for a pueblo, if some means of access could be de-

vised, but it could not have been freer of all traces of former occupation if it had been thoroughly swept up the day before. Only once was it that a doubt crossed my mind, when I came across a cairnlike monument which looked as though it might have been constructed by human hands. But the possibility of its being the result of erosion is also quite as strong as the other. No bits of pottery, no broken household utensils of any sort, no traces of construction of any sort were visible, not even the deepening of the natural surface of any of the rock cavities for the purpose of rain-water storage for drinking use, betrayed even the slightest indication that the top of the Mesa had ever been the prehistoric home of the Acomas.''

In *Harper's Weekly* (August 28) Professor Libbey makes the following statement:

'' There were no remnants of pottery, or fragments of household utensils, or implements of any kind; no water-tanks for the storage of rain water; one object alone looked as though it might have been built by human hands, and that was a small cairnlike mass of stones.''

In this article Professor Libbey pictures the operation of his gun, boatswain's chair, etc.; but where is the 'cairnlike mass of stones' which he found, the origin of which he seems to be at such a loss to determine? It seems to me that this doubtful feature is the most important of all the observations made by Professor Libbey during his brief stay on the summit, and yet he left it unphotographed.

Later, in the *Philadelphia Press* (October 10), Professor Libbey says:

'' The cairn-like pile of rocks, which I am glad Mr. Hodge so clearly decides is a cairn, is possibly the best proof of a mere visit, for even primitive people are not given to building cairns in their back yards. * * * *

''I am inclined from the facts which I was able to observe upon the top of the Mesa *still* (*!*) to believe that while the top may have been visited, no evidence exists at present of its ever having been permanently inhabited.

''I picked up some fragments which resembled ancient pottery, but could not persuade myself that they were. I took them to Mr. Pearce [one of the reporters who accompanied Professor Libbey], and he agreed with me that they were not pottery.''

The fact that the Professor fails to speak of having occupied part of his precious two hours in the erection of the lichen-covered rock-pile which we found and photographed, and the fact also that the structure occurs on a spot so protected from the surface wash that it may have stood there for ages, were sufficient to mislead anyone, and my error may be regarded as acknowledged when Professor Libbey states openly that the monument was erected by himself.

The better part of two days of research by the members of my party, each of whom had his eyes open, failed to reveal any other artificial monument than the one which I have figured. I am, therefore, safe in concluding that there is no ground whatever for the belief that any other artificial cairn or cairn-like structure exists on the summit of the Enchanted Mesa. If Professor Libbey constructed the cairn referred to, then he might have spent the portion of the two hours consumed by its erection in a way more profitable to archæology. Whether or not it was erected by him, the evidence of the former occupancy of the summit of the Enchanted Mesa is not weakened in the slightest degree.

F. W. HODGE.

BUREAU OF AMERICAN ETHNOLOGY,
WASHINGTON, December 14, 1897.

LAMARCK AND THE 'PERFECTING TENDENCY.'

IN preparing some lectures on the history of evolution theories I have come across a curious difference of opinion among distinguished writers. Professor Osborn ('From the Greeks to Darwin,' p. 163) seems to contradict himself in the same paragraph. He says: ''Lamarck believes that we see in nature a certain natural order imposed by its Author, which is manifested in the successive development of life; we thus study natural forces and nature abandoned to its laws. In this sense we see nature creating and developing without cessation towards higher and higher types. External conditions do not alter this order of development, but give it infinite variety by directing the scale of being into an infinite number of branches.''

This statement might, without violence, be paraphrased by saying: "Lamarck believed in a tendency toward perfection, modified by external conditions;" which I believe to be strictly correct. But Professor Osborn's next sentence is: "Lamarck denied, absolutely, the existence of any 'perfecting tendency' in nature, and regarded evolution as the final necessary effect of surrounding conditions on life."

On looking up other writers I found that a belief in a perfecting tendency is ascribed to Lamarck by Lyell (Principles, Vol. II., p. 259), Darwin (Origin, Amer. ed., I., pp. xv+153, and Life, I., p. 384), Spencer (Biology, Section 146), Romanes (Darwin and after Darwin, I., p. 255). Perrier (Phil. Zool. avant Darwin, p. 84) argues strongly on the same side. Strangely enough, Quatrefages (Darwin et ses Précurseurs Français, p. 65) takes quite the opposite view, and directly accuses Darwin of error. I have been unable to consult any of Lamarck's works except the Philosophie Zoologique, but so far as that is concerned the majority view seems to be the correct one. Throughout, though Lamarck does not exactly use the expression 'perfecting tendency,' he distinguishes between two things—one, the *échelle*, the *dégradation* or *gradation* of organisms, their tendency to *composition* (complication, advancement); the other, the influence of environment in altering their needs and thus their structure. The *échelle* is a pre-established order through which organisms have progressively evolved, but visible only in its grand outlines, because changing conditions have indirectly altered the form of the organisms, especially externally, and thus obscured the details.

A pre-established order of evolution from the lowest to the highest forms seems to amount to the same thing as a tendency towards perfection.

I have been unable to find any passages which can be construed as an absolute denial of a perfecting tendency, but I have found a good many which indicate that Lamarck believed in it; whether or not because he was unable to suggest anything better to account for the progressive evolution which he saw, who can say? The following are sufficiently good examples:

"La puissance absolue du sublime Auteur de toutes choses, n'a-t-elle pu créer un *ordre de choses* qui donnât successivement l'existence à tout ce que nous voyons comme à tout ce qui existe et que nous ne connaissons pas?" (Phil. Zool. ed. 1873, I. p. 74.)

"Je vais faire voir que la nature en donnant, a l'aide de beaucoup de temps, l'existence à tous les animaux et à tous les végétaux, a réellement formé dans chacun de ces régnes une véritable échelle, rélativement à la composition croissante de l'organisation de ces étres vivants, mais que cette échelle, qu'il s'agit de reconnaître, en rapprochant les objets, d'après leurs-rapports naturels, n'offre des degrès saisissables que dans les masses principales de la série générale, et non dans les espéces ni même dans les genres: la raison de cette particularité vient de ce que l'extrême diversité des circonstances dans lesquelles se trouvent les différentes races d'animaux et de végétaux n'est point en rapport avec la composition croissante de l'organisation parmi eux, ce que je ferai voir, et qu'elle fait naître dans les formes et les caractères extérieurs des anomalies ou des espèces d'écarts que la composition croissante de l'organisation n'aurait pu seule occasionner." (l. c., p. 121.)

On page 144 Lamarck says: "Il est évident que si la nature n'eut donné l'existence qu'à des animaux aquatiques, et que ces animaux eussent tous et toujours vécu dans le même climat, la même sorte d'eau, la même profondeur, etc., sans doute alors on eût trouvé dans l'organisation de ces animaux une gradation régulière et même nuancée." And then he shows that differences in the composition, depth, etc., of the water have brought about disturbances in the regularity of the gradation. Lamarck invariably uses *gradation* in the sense of an upward series, opposing it to *dégradation*, a downward series.

A very important passage is that quoted by Perrier from Phil. Zool., p. 114. Lamarck states the struggle for existence according to his imperfect conception of it, showing how big and little animals alike are kept within due bounds. He concludes: "Ainsi par ces sages précautions tout se conserve dans l'ordre établi; les changements et les renouvellements perpétuels qui

s'observent dans cet ordre sont maintenus dans des bornes qu'ils ne sauraient dépasser; les races des corps vivants subsistent toutes, malgré leurs variations; les progrès acquis dans le *perfectionnement* de l'organisation ne se perdent point; tout ce qui paraît désordre, renversement, anomalie, rentre sans cesse dans l'ordre général et même y concourt; et partout et toujours la volonté du sublime Auteur de la nature et de tout ce qui existe est invariablement exécutée." Lamarck rather rarely uses the word *perfectionnement*; hence I have italicized it.

The passage concerning the aquatic animals very clearly shows a belief in a tendency toward perfection apart from other factors. The other passages, especially the last, are fully confirmatory.

I have been unable to consult the Histoire Naturelle, except as quoted by Professor Osborn and others. Possibly it is there that Professor Osborn finds authority for the statement that Lamarck denied absolutely the existence of a perfecting tendency. But so far as the Philosophie Zoologique is concerned the case is clear.

The point I have raised is important now only as a matter of history, but in the interest of accuracy it seems desirable that Lamarck's true views should be emphasized. It would appear that he was not 'completely carried away with the belief that his theory of the transmission of acquired characters was adequate to explain all the phenomena' (Osborn l. c., p. 180); rather, the 'Lamarckian factor' played a subordinate part in his scheme of evolution. And, if this interpretation be correct, it would seem that Darwin's criticisms of Lamarck are more nearly just than is generally supposed, and that, as Perrier says, he was, 'by an astonishing contradiction, at once a finalist in his general views, and a determined opponent of final causes in details.'

JOHN GARDINER.

UNIVERSITY OF COLORADO, BOULDER, COLO.

MEMORIAL MEETING COMMEMORATIVE OF ALLEN AND HORN.

A GENERAL invitation is extended to all those interested to be present at a memorial meeting, commemorative of Harrison Allen, M.D., and George H. Horn, M.D., to be held in the library hall of the Academy of Natural Sciences of Philadelphia, on Friday evening, December 31st, at eight o'clock. The following gentlemen will make addresses:

Dr. Edw. J. Nolan, 'The Relations of Doctors Allen and Horn to the Academy and other Societies.'

Mr. S. N. Rhoads, 'Dr. Allen's Work in Zoology.'

Dr. D. G. Brinton, 'Dr. Allen's Contributions to Anthropology.'

Professor John B. Smith, Sc.D., 'Dr. Horn's Contributions to Coleopterology.'

Rev. Henry C. McCook, D.D., 'Dr. Horn as a Physician and Naturalist.'

E. G. CONKLIN, PH.D.,
J. CHESTON MORRIS, M.D.,
D. G. BRINTON, M.D.,
REV. HENRY C. MCCOOK, D.D.,
HENRY SKINNER, M.D., *Ch'm.*
Committee.

LOGAN SQUARE.

SCIENTIFIC LITERATURE.

Memorials of William Cranch Bond, Director of the Harvard College Observatory 1840–1859, and of his son, George Phillips Bond, Director of the Harvard College Observatory 1859–1865. EDWARD S. HOLDEN. San Francisco. 1897. Pp. iii+296. 8oc. With illustrations.

In this work Professor Holden has given a most interesting account of the two men who established the Observatory of Harvard College and carried it on for its first quarter of a century—a time of great importance for the development of astronomy in this country.

In 1840 the beginnings of permanent observatories in this country had already been made; in 1865 the Observatory at Cambridge had acquired, under the Bonds, a recognized position in the astronomical world, and the Bonds had contributed to the general progress of the science.

Professor Holden's work has been rendered important, and at the same time difficult and thankless, by circumstances which he finds

himself compelled to mention. It cannot be called a history of American astronomy for the quarter of a century in question, but Professor Holden has furnished, with the help of the family of the Bonds, a valuable contribution thereto.

The most troublesome part of the author's task has been to rightly explain the long and persistent unfriendliness of prominent American astronomers to the new institution and its conductors. W. C. Bond was one of those quiet artists who so often do admirable service to the science in an unpretending way without making claim to the position of a great theoretical astronomer.

The first difficult task for Professor Holden has been to give the history of chronographic registration and the part of the Bonds in the invention.

Wilkes in 1844 (p. 239) made the first experiment for determining longitude by the electric telegraph between Washington and Baltimore. Sears C. Walker, a most able astronomer, gives in *Silliman's Journal*, Second Series, Vol. VII., pages 206 to 217, a report to Dr. A. D. Bache, then Superintendent of the Coast Survey, in which the history of the first experiments in chronographic registration is well told. Professor Holden mentions the subsequent experiments of 1847 and 1848 to render the telegraphic method thoroughly practicable for longitude determinations.

In Loomis's 'Recent Progress of Astronomy' (New York, 1850) we find the actual results of the longitude operations of the summer of 1847 conducted between Philadelphia, Washington and Jersey City, from which Loomis draws the inference: "These experiments seem to authorize the conclusion that the electric telegraph affords the best means for the determination of terrestrial longitude between places in telegraphic connection with each other." This inference of Loomis has been confirmed by subsequent experience.

Walker, in his article before cited, mentions the experiments of Locke, Mitchell and others, and dwells greatly on the merit of the proposed 'automatic clock register,' and of the principle of chronographic registration for all time-observations.

Locke's part in the experiment seems to have been to arrange, under Walker's direction, apparatus for making and breaking circuit without damage to the clock. Mitchel, on the other hand, suggested a form of chronograph not suitable in Walker's opinion for nice astronomical observations.

The apparatuses of both Locke and Mitchel were tried in 1848 under Walker's direction. On the whole, Professor Holden has well stated the history; some points are obscure in all the accounts, and it requires a careful reading and putting together of the literature of the subject to rightly assign priority in the different parts of the invention, in which howsoever we combine the materials; the principal figures are Walker and W. C. Bond, and the subordinate ones are Locke and Mitchel.

Bond's chronograph was exhibited at the Great Exposition of 1851 in London, and distinguished with a gold medal. These circumstances seem to have led to the introduction of chronographic registration at Greenwich in 1854. Thence it spread rather slowly over the Continent; it was adopted for standard right ascension at Pulkova in 1861, but the eye and ear method was still retained there for polar stars and secondary catalogues, in which it has some advantages, especially in respect of personal equations. In America the chronographic method has been used quite generally, and the Bond chronograph has become a standard instrument. It has been used at the Harvard College Observatory from its first construction in 1850 to the present time. It served for the zone 50°–55° of the catalogue of the Astronomische Gesellschaft, as well as for the Bonds' own zones of small stars observed in 1852–53, and other work executed during their successive directorships and later.

Other difficult matters of the history of the Observatory are stated by Professor Holden with due regard for the feelings of the representatives of the astronomers of the last generation. The Perkins professor of astronomy when W. C. Bond removed to Cambridge in 1838 and began the duties of his office was Benjamin Peirce, one of the most eminent mathematical astronomers of his day. It is rather difficult, as Professor Holden im-

plies on pages 36 and 37, to understand the whole matter, without alluding to 'grievances half a century old.' W. C. Bond became, in 1838, 'astronomical observer' without salary except the rent of a dwelling house, and without definite relations to the younger 'Perkins professor.' Peirce, perhaps, expected rather too early from the new establishment results which could be 'passed over to the computer.' G. P. Bond, B. A. (Harvard), 1845, was a diligent student of astronomy in all its branches, and soon showed himself capable of improving the methods of computation, as is shown by his early papers, especially 'Some Applications of the Method of Mechanical Quadratures'—a paper which anticipated an important method of Encke's, and which affords ideas not yet completely worked out. One of the few papers which he contributed to the *Astronomical Journal* is entitled 'On the Orbit of Wilmot's Comet,' and employs methods of his own which deserve study.

When W. C. Bond passed away in 1859, at the age of 70, his son had long been the chief assistant in the Observatory, and succeeded quite naturally to his father's place, but Peirce had been himself a candidate, and circumstances had brought about an estrangement between him and Bond, but the latter seems to have done his best to renew pleasant relations.

Other matters, easily traced, are involved in the reasons why these relations were not renewed. Professor Holden alludes to the circumstance that George Bond was not selected as an original member of the National Academy of Sciences as a matter requiring explanation. But this concerns the history of American science in general, and not merely the few persons who may have made up the list submitted to Congress. It is not best to imply here that the omission was more unfair than similar transactions are often liable to be.

At the time, 1863, when the National Academy was founded, Bond had been four years Director of Harvard College Observatory, and had shown in that capacity ample knowledge of mathematics and astronomy to fill the position completely. He had gathered around him a corps of hard working assistants, among them Asaph Hall. The meagre salaries which the College could pay were rendered still more inadequate by the war then prevailing, and the corps of astronomers was diminished by the call for soldiers. One able and enthusiastic observer, Sidney Coolidge, fell in the battle of Chickamauga. The remainder of the assistants were compelled, with one exception, to seek occupation elsewhere. Bond himself struggled on heroically, although stricken with a mortal disease, and finally passed away at his post in 1865, before the close of the war, after completing the great work on Donati's Comet of 1858, the first work of an American astronomer to be rewarded with the gold medal of the Royal Astronomical Society. The vindication of the wisdom of his appointment as Director was complete, but he never received the medal which reached America a short time after his death.

Professor Holden's book has been put together from G. P. Bond's diaries and correspondence, and with the zealous cooperation of his family, Mrs. Richard Bond and his daughters. The author's work is, on the whole, well and judiciously done; some trifling defects are apparently due to unfavorable circumstances; such, for instance, are the want of a subject index; the Index of Proper Names is very defective; the spelling of German names like Brünnow and Rümker is not correct, and the use of capitals to indicate names of persons is a technical practice not approved in general literature. While the book is not a complete history of astronomy in America from 1840 to 1865, it affords precious materials for such a history, and should be read by all who desire to follow out that period of our science, and at the same time to become acquainted with two of its most prominent and faithful workers in the traditional as well as in the newer astronomy. G. P. Bond's experiments in astronomical photography were of very great importance and, in fact, were prior even to Rutherfurd's.

TRUMAN HENRY SAFFORD.

WILLIAMS COLLEGE.

Handbuch der Klimatologie. Von DR. JULIUS HANN. Stuttgart, Germany, J. Engelhorn. 1897. Second edition. 3 vols. 36 Marks.

If I were asked to mention the greatest authority on matters pertaining to climate and

climatology I should give, without hesitancy, the name of Dr. Julius Hann, the director of the Austrian meteorological service.

In 1883 Dr. Hann published a long needed book, a general treatise on the climatology of the whole earth's surface. This work was the outcome of many years of special study and research, and required several years of direct labor in its actual writing. It was received with enthusiasm by the German reading scientific public, and English readers deplored the fact that we had no corresponding work in English. Fourteen years have now elapsed since Hann's work first appeared, and its second and greatly enlarged and rewritten edition finds our language still without any general work on climatology. We have not even a translation to fill the place which should be occupied by a work of honest English or American authorship, and it is to be hoped that some publisher will be induced to take advantage of the appearance of this new German work by bringing out a translation of it either in full or in abridgment.

Hann's climatology consists of three volumes. The first is devoted to general climatological conditions, in which the relations of cause and effect are discussed for the various meteorological elements. The second volume is devoted to the special climatology of the regions embraced in the tropical zone. The third volume treats of the climate of the temperate and cold zones.

One serious drawback to the usefulness of the work is the lack of climatological charts; but the author explains that they were omitted because they would considerably increase the price that must be asked of purchasers of the present treatise, and, moreover, such charts had been published elsewhere in easily accessible form.

The 404 pages of Vol. I. contain: A general idea of the scope of climatology; and complete explanations of the nature, importance and relation to each other of the climatic factors, temperature, humidity, precipitation, cloudiness, wind, air pressure and evaporation. A short statement of the composition of the air and the impurities which it may contain, together with some remarks on plant phenology as related to, and dependent on, climatic conditions. A brief though comprehensive review of our knowledge of the amount of radiation from the sun and the resulting 'solar climate.' The principal forms of telluric or physical climate, which is the solar climate modified by the earth's atmosphere and the existing distribution of land and water; this naturally occupies the greater portion of Vol. I. And, finally, the meteorological cycles and climatic oscillations.

Let us notice more particularly some of the most interesting facts given by the author.

Owing to the elliptic form of the earth's orbit, by which the earth is sometimes a little nearer the sun than at other times, the southern hemisphere receives more solar heat in summer and less in winter than the northern hemisphere. If our earth had no atmosphere the average temperature at the earth's surface would be, *at the equator* for the hottest month 67°C. and for the coldest month 56°C., and *at the poles* for the hottest month 82°C. and for the coldest month —273C. (which latter is, curiously enough, the absolute zero of the thermometric scale).

Concerning the interesting question of the effects of forests on rainfall Hann says that from the nature of the case it is almost impossible to prove anything by direct measurements, and that the increase of rainfall due to forest growth has been far over-estimated. It is quite probable, however, that in the tropics the woods do slightly increase the amount of precipitation, and extensive woods in the middle and higher latitudes probably increase the frequency of rainfall.

The effects of mountains on rainfall has received thorough treatment at the hands of the author, and especially that peculiar phase of increase of rainfall with the altitude up to a certain level, and the subsequent gradual decrease at greater heights. With an increase of altitude amounting to from 2,000 to 4,000 feet the rainfall may be increased by from 50 to 250 per cent. This increase of rainfall is due to the condensation of the moisture in ascending air currents which form on mountain sides.

It has been computed, retrospectively, that in Jurassic times the mean temperature of the earth was about 2°C. warmer than it is at pres-

ent. At about Lat. 30° N. it was colder, but in other latitudes warmer, and at the equator about 6.5°C. warmer then than now.

The decrease of air temperature with the increase of altitude above the sea-level is of very great importance in climatological considerations, and Hann has given a careful discussion of this phenomenon.

The average decrease of temperature in mountain regions is 0.57°C. per 100 meters ascent, and it seems to be quite uniform for both equatorial and arctic regions. For the very gradual ascents, such as long slopes, the temperature decrease is but about 0.40°C. per 100 meters ascent; while for the free air it is probably about 0.65°C. These values show considerable retardation of the dynamic change of temperature, which is about 1°C. per 100 meters ascent.

Among the peculiar winds none are more interesting than the hot, dry winds which occur in certain mountain regions, and which in Europe are known as Foehn winds, and in the United States as Chinook winds. It was to have been expected that Dr. Hann would devote considerable space to these winds, because they are with him a pet subject; although his modesty has caused him to place his first contribution to its literature a long way down in the reference list, whereas it should have headed that bibliography. Probably no single class of winds have been so little understood as these Foehn winds; and after searching in all directions for some reason for their existence, the simple theory that they are due to the dynamic heating of descending air masses which have a decreased relative humidity due to the increased temperature has sufficed to explain what was considered a most complex phenomenon.

One very interesting problem in climatology is, to determine how the different elements, such as temperature, rainfall and cloudiness, vary with changes of latitude. This is shown by finding the average values of the elements for certain parallels of latitude throughout their whole length as they encircle the globe.

The following little table gives for various latitudes the average temperature for the whole year in degrees Fahrenheit; the average total annual depth of precipitation (which includes both rainfall and snowfall) in inches; and the average annual amount of cloudiness measured on a scale of 0 = a clear sky, and 100 = a sky entirely overcast with clouds.

Lat.	Temp.	Precip. inch.	Cloud per cent.
N. 80°	2°	14	—
70	14°	14	59
60	30°	19	61
50	42°	23	58
40	57°	21	49
30	68°	24	42
20	77°	32	40
N. 10	80°	76	50
Equator	79°	77	58
S. 10°	78°	67	57
20	74°	30	48
30	65°	26	46
40	54°	37	56
50	42°	46	66
S. 60°	31°	[40]	75

This table is also interesting from the fact that it indicates that we have meteorological observations 20° nearer the pole in the northern hemisphere than in the southern hemisphere.

The last section of this volume, which treats of climatic changes, may be divided into two parts —that treating of changes in geologic times, and that of changes shown by the records of modern civilization. This last has already been given to readers of meteorological literature in Brückner's *Klimaschwankungen*, and this same authority is freely quoted by Hann. But the outline of the various theories accounting for climatic changes in the distant past is a much needed summary. Hann states briefly the main theories which have been promulgated and which depend on possible changes in the inclination of the ecliptic, or in the eccentricity of the earth's orbit. A rough computation convinces him that the effects of neither of these would account for the changes which must have taken place in the earth's climate. Croll's theory is given due prominence, but Hann finds it unsatisfactory. A theory developed by Luigi de Marchi makes a variation in the coefficient of transmission of solar radiation through our atmosphere the important factor in these great climatic changes; but no certain causes of increase or decrease in the amounts of water vapor or carbonic acid gas, which would mainly affect the values of this coefficient, have been pointed out as appli-

cable to the existing case without any manner of doubt. The mystery of the great ice age, and of the former rich vegetation in the present cold zone, still remains to be solved.

FRANK WALDO.

An Outline of the Theory of Solutions, and Its Results, for Chemists and Electricians. By J. LIVINGSTON R. MORGAN, PH.D. (Leipzig), Instructor in Quantitative Analysis, Polytechnic Institute, Brooklyn. New York, John Wiley & Sons; London, Chapman & Hall. 1897. Pp. 63.

The contents of this work are four lectures, delivered before the Brooklyn Institute of Arts and Sciences, and deal with the theory of solutions, methods for the determination of electrolytic dissociation, the theory of the voltaic cell, and analytical chemistry from the standpoint of electrolytic disociation.

The author states in his preface that "a knowledge of the theory of solution and its results, is so important to workers in all branches of chemistry and electricity, that the following pages have been compiled, containing an elementary treatment of the subject." * * * "If by this sketch the author can induce any one to go deeper into the subject he will feel more than repaid for his work."

H. C. J.

Untersuchungen über das Erfrieren der Pflanzen. MOLISCH. Jena, Gustav Fischer. 1897. Pp. viii + 73. 11 illustrations.

A notable addition to the physiology of the cell has been recently published by Professor Molisch as a result of several years' work upon the effect of cold upon plants.

The researches upon which generalizations rest are fragmentary and necessarily inaccurate, since they were carried on in the open air or under conditions of great discomfort to the observer. At the same time no regulation of the temperature could be effected. Dr. Molisch has been enabled to obtain results of great importance, both from the advance in cell physics since the time of Muller's experiments and by the use of ingeniously constructed apparatus.

Dr. Molisch's researches were chiefly conducted by means of a double-walled freezing chamber of wood 33 x 33 x 27 cm. outside measurements. The space of 7 cm. between the double walls on five sides of the chamber was filled with sawdust. The center of the chamber was occupied by a zinc compartment to contain a microscope. A tubulated opening through the walls of the zinc and wooden compartments allowed access of light to the mirror, and toothed rods for adjustment of the stage, objectives and mirror extended outside the walls. The space surrounding the zinc compartment was filled with a mixture of salt and ice, by which temperatures of 4°C. to 10°C. were obtained in a room kept at 10°C.

As a useful preliminary, observations were made upon the freezing of colloidal substances, emulsions, color and salt solutions. The crystals were seen to appear suddenly in a colloid, such as gelatine, and to increase in size, extracting the water from the gelatine, so that the latter shrunk into a network resembling parenchyma tissue. Some colloids return to the original condition upon thawing; others do not. Starch paste is an example of the latter. The suspended particles in an emulsion, such as latex, aggregate in the form of a network of bands upon freezing. Freezing of color and salt solutions result in the more or less complete separation of the solid and solvent.

The chief interest of the paper lies in the results of the direct and continuous observation of the freezing of living cells.

An amœba, after exposure of 25 minutes to a temperature of 9°C., exhibited the formation of clumps of ice crystals in the plasma, and finally became a solid lump consisting of a complicated network of plasma almost devoid of water, ice crystals, vacuoles of concentrated cell-sap and air-bubbles. The slender filaments of Phycomyces froze only when the temperature fell to —17° C. The small diameter of the cells seem to be a direct adaptation against freezing. Yeast cells exhibited a shrinkage of 10 per cent., due to loss of water when the medium was frozen, but the cells were not killed at –15°C. The freezing of Spirogyra filaments at –3 to –6°C. is accompanied by a shrinkage in diameter amounting to 62 per cent. and by the final aggregation of chlorophyll band and nucleus in the center of the cells. The excretion of water in this plant under low temperatures may be easily observed

if a specimen is mounted in olive oil. The excretion of water from the cells soon begins and a cylinder of ice is formed about the filament.

As a result of the work upon unicellular structures in many organisms, it is found that the freezing may be accompanied by the formation of ice in the cell, external to the cell membrane or in both places. In either case it is accompanied by a more or less complete separation of the water from the plasma. The exposure of tissues with strongly developed walls to low temperatures was accompanied by the excretion of ice into the intercellular spaces, followed by the formation of ice both here and in the cell. Not all the cells of a plant exhibit the same resistance to cold. A temperature of a few degrees below zero Centigrade may freeze a leaf while the guard cells and hairs will remain intact. These cells are likewise highly resistant to heat and other agencies, as Leitgeb has previously demonstrated.

The question as to the death of a plant upon freezing or consequent thawing has engaged the attention of a large number of workers. Molisch's results prove that generally the death of a plant is due to the direct action of cold upon the plasma, and that the consequent thawing does not matter whether slow or rapid, in air or water. To this generalization an exception is offered by the experience of Müller-Thurgau, who found that frozen fruits of the apple and pear were not destroyed if thawed slowly, a fact long known in household practice, and the experiment of Molisch with *Agave americana*, which behaved in a similar manner. These exceptions, of course, rest upon the provision that the temperature has not fallen below a certain limit.

The death of plants from temperatures above the freezing point may result from disturbances of the metabolic processes or the transpiratory activity. In the latter instance the 'frosting' of a plant is due to the decreased osmotic activity of the root hairs under low temperatures, and wilting of the leaves consequent upon an insufficient supply of water. Dr. Molisch is mistaken in attributing the origin of this idea to Krabbe, as the principle has been known for many years, although its detailed application was first exploited by Krabbe.

Among the plants which are killed by low temperatures above freezing point, the most delicately responsive are *Episcia discolor* Hook., *Sanchezia nobilis* Hook., *Eranthemum tricolor* Nichols., *E. couperi* Hook., *E. igneum* Linden., *Anœctochilus setaceous* Blume. The species in this list exhibit damage after exposure to temperatures 1.4° C. to 3.7° C. for periods of 18 to 100 hours. *Begonia stigmatosa*, *B. scandens*, *Bœhmeria argentea* Linden, *Tradescantia discolor*, *T. zebrina*, and *Euphorbia splendens*, *Ficus elastica*, *Gloxinia hybrida*, *Tropæolum majus*, are examples of a numerous class which are injured by longer exposure to the same temperature. It is to be seen that Molisch's carefully attained results sustain the contention of Goeppert and Müller-Thurgau that death from freezing is due to the formation of ice or to the direct influence of cold, and not to the processes of thawing as maintained by Sachs. The formation of ice entails the excretion of water from the protoplasm, and the great and rapid loss of the fluid results in the architectural disintegration of the plasma. The disintegration may be hastened by the poisonous action of concentrated cell-sap remaining.

So far as the results are at hand, it is to be said that the excretion of water by cells at low temperatures is not only a physical reaction, but this action has become under the direction of the protoplasm a protective adaptation. A second adaptation consists in the smallness of the cell.

D. T. MACDOUGALL.

SOCIETIES AND ACADEMIES.

BOSTON SOCIETY OF NATURAL HISTORY.

THE Society met December 1st; thirty-five persons present. Professor N. S. Shaler, in discussing Aeolian deposits in relation to the formation of river valleys, gave the result of his observations in Utah and Montana. Along the Ruby river, where the vegetation is dense and the soil rich, the loess is held and the valley built up. In Montana below 7,000 feet the vegetation is thin and insufficient to inhibit.

Mr. A. W. Grabau showed some fossils from the upper Devonian of western New York, and gave the views taken by various investigators as to the nature of Conodonts, since their discovery by Pander in the Silurian and Devonian

rocks of Russia. Mr. Grabau's studies confirm the position taken by Zittel and Rohon that these minute tooth-like fossils are the jaws of worms. He also discussed the relations of Styliolina, Cardiola and Clymenia, and the close parallelism between American and European Goniatites. Professor Hyatt took exception to Hinde's view, quoted by Mr. Grabau, as to the unity of the American and European forms; the late American faunas are residual; they do not originate types; the very ancient American faunas may be, however, originating faunas.

Dr. Jackson drew attention to the large numbers of associated fossils in very small space, and Mr. Grabau stated that Clark's investigations proved the identity of the American and European species.

SAMUEL HENSHAW,
Secretary.

THE TORREY BOTANICAL CLUB, NOVEMBER 9, 1897.

THE paper of the evening, by Mrs. E. G. Britton, a description of two new species of *Ophioglossum* will be printed in the *Bulletin.* The paper also discussed the affinities, range and type characters of our Eastern species of *Ophioglossum*, with keys and specific descriptions, and with exhibition of tracings and numerous mounted specimens.

Dr. Underwood sketched the characteristics of the four distinct types of *Ophioglossum* as: 1st, the section typified by *O. vulgatum* and discussed in the paper; 2d, that by *O. palmatum* of tropical America, which extends into Florida, there growing directly under the crown of the palmetto trees, nestled among the leaf-shrubs; 3d, that typified by *O. pendulum*, found in the Hawaiian Islands and Pacific regions, which is also pendulous from trees and produces a stipe attached almost to the middle of the leaf. In the 4th section, with growth not over one inch high, the sterile and fertile fronds are distinct to the rooting base.

Dr. Underwood further remarked the necessity of experience to discover forms of *Ophioglossum*, especially such as *O. crotallophoroides*, only one inch high, collected by him in Alabama.

Mr. Clute spoke of the great diversity in size displayed by *O. vulgatum* in a single locality.

Professor Burgess referred to the occasional occurrence of *O. vulgatum* with its own namesake *Pogonia ophioglossoides*, and to other companion-plants with which he finds *Ophioglossum* associated in growth, as *Chiogenes* and especially the orchids *Microstylis ophioglossoides*, *Habenaria hyperborea* and *H. dilatata.*

Dr. Underwood then exhibited photographs of the Kew Gardens, with reminiscences of his visit of last summer. He spoke particularly of their formal decoration, dating back to royal use, and the photographs shown included one of 'Queen Mary's Elm,' planted by her about 1555, once 25 feet in girth, now represented chiefly by a series of shoots.

EDWARD S. BURGESS,
Secretary.

THE ACADEMY OF SCIENCE OF ST. LOUIS.

AT the meeting of the Academy of Science of St. Louis on December 20, 1897, twenty-five persons present, Dr. R. J. Terry exhibited several specimens of human humerus, showing supracondylar process associated with high division of the brachial artery, which was contrasted with similar processes that have been observed in the anthropoid apes and the lower monkeys, and with a similarly situated foramen of the arm of the *Felidæ.* It was stated that while a slight roughness was observed, at the point indicated, in a majority of ninety-six specimens observed, the structure was fairly developed in four out of this number, in all cases on the left arm.

Professor F. E. Nipher presented a paper describing a long series of experiments made to determine the distribution of pressure over a pressure board, and summarizing the results reached.

WILLIAM TRELEASE,
Recording Secretary.

SCIENCE

A WEEKLY JOURNAL DEVOTED TO THE ADVANCEMENT OF SCIENCE.

EDITORIAL COMMITTEE: S. NEWCOMB, Mathematics; R. S. WOODWARD, Mechanics; E. C. PICKERING, Astronomy; T. C. MENDENHALL, Physics; R. H. THURSTON, Engineering; IRA REMSEN, Chemistry; J. LE CONTE, Geology; W. M. DAVIS, Physiography; O. C. MARSH, Paleontology; W. K. BROOKS, C. HART MERRIAM, Zoology; S. H. SCUDDER, Entomology; C. E. BESSEY, N. L. BRITTON, Botany; HENRY F. OSBORN, General Biology; C. S. MINOT, Embryology, Histology; H. P. BOWDITCH, Physiology; J. S. BILLINGS, Hygiene; J. MCKEEN CATTELL, Psychology; DANIEL G. BRINTON, J. W. POWELL, Anthropology.

Published by

THE MACMILLAN COMPANY, 66 Fifth Ave., New York.

*TO OUR READERS.**

THE experience of centuries shows that great success in advancing scientific knowledge cannot be expected even from the most gifted men, so long as they remain isolated. The attrition of like minds is almost as necessary to intellectual production as companionship is to conversation. The commencement of the development of science on a large scale, and with brilliant success, was coeval with the formation of the Royal Society of London and the Academy of Sciences of France. When these bodies came together their members began to talk and to think.

At the present day one of the aspects of American science which most strikes us is the comparative deficiency of the social element. We have indeed numerous local scientific societies, many of which are meeting with marked success. But these bodies cannot supply the want of national coöperation and communication. The field of each is necessarily limited, and its activities confined to its own neighborhood. We need a broader sympathy and easier communication between widely separated men in every part of the country. Our journal aims to supply the want of such a medium, and asks the aid of all concerned in making its efforts successful. It will have little space for technicalities which interest only the specialist of each class, and will occupy itself mostly with those broader aspects of thought and culture which are of interest not only to scientific investigators, but to educated men of every profession. A specialist of one department may know little more of the work of a specialist in another department than does the general reader. Hence, by appealing to the interests of the latter, we do not neglect those of the scientific profession. At the same time, it is intended that the journal shall be much more than a medium for the popularization of science. Underlying the process of specialization, which is so prominent a feature of all the knowledge of our time, there is now to be seen a tendency toward unification, a development of principles which connect a constantly increasing number of special branches. The meeting of all students of nature in a single field thus becomes more and more feasible, and in promoting intercourse among all such students SCIENCE hopes to find a field for its energies, in which it may invite the support of all who sympathize with its aim.

*From the Introduction to the new series of SCIENCE by Professor Newcomb.

An Advertisement of Science.

The first series of Science.

When SCIENCE was established, in 1883, it was at once accepted as the organ of American men of science. Edited by Mr. S. H. Scudder, it early numbered among its contributors nearly all the leading scientific men of the country. The officers and directors of the JOURNAL were: President D. C. Gilman, *President*; Professor Simon Newcomb, *Vice-President*; Hon. Gardiner G. Hubbard, Professor Alexander Graham Bell, Professor O. C. Marsh, Major J. W. Powell, Professor W. P. Trowbridge and Mr. S. H. Scudder.

The sum of eighty thousand dollars was spent in the establishment and support of SCIENCE by Professor A. Graham Bell and the late Mr. Gardiner G. Hubbard. Large as the sum may appear, it is small in comparison with the value of the JOURNAL to science in America.

The new series of Science.

SCIENCE was reorganized three years ago, and has since been under the charge of an editorial committee, consisting of the leading men of science of America. It has, during this period, adequately and fully reflected the progress of science and has been an important factor in its advancement. Its contents have maintained a high and even standard, comparing favorably with any journal in any country. It has stimulated scientific activity and interest in America, and has led to a fuller recognition of American science abroad.

Original Contributions.

SCIENCE aims to give each week just what everyone interested in the advancement of science should read. There are articles and addresses, often by our leading students of science, and always by the most competent writers. These do not conflict with the contents of the special journals, but offer the information and stimulus needed by those who wish to keep abreast of modern science. For example, SCIENCE published an account, by Lord Rayleigh, of the discovery of argon; the first English announcement of *Pithecanthropus erectus*, by Professor Brinton; the first English description of Professor Röntgen's discovery, by Professor Münsterberg, together with the American researches on the subject by Professors Rood, Mayer, Pupin and others; the announcement, by Professors Langley and Bell, of the successful trial of the aërodrome; an article, the best hitherto written, on Acetelene, by President Crafts. The most important recent biological advance, organic selection, was first announced and discussed in SCIENCE by Professors Baldwin, Osborn, Lloyd Morgan and Poulton. Addresses and articles have been contributed by Professor Newcomb, Lord Kelvin, Lord Lister, Professor Foster, President Mendenhall, Mr. Gilbert, Mr. Scudder, Professors Gibbs, Marsh, Remsen, Bowditch, Minot, Brooks, Le Conte, Billings, and the leaders in all departments of science, including Goode, Cope, Allen and others no longer living.

Organization of Science.

All matters relating to the organization of science, associations, academies and societies, journals, universities, museums and other institutions, both here and abroad, the scientific departments under the government, legislation and related subjects have been fully reported and discussed in SCIENCE. Thus, for example: The American Association for the Advancement of Science, the National Academy of Sciences, the various national societies devoted to a special science, the State and local academies and societies, have had their proceedings reported, and not by writers for the press, but by officers of the societies. SCIENCE has published the report of the Forestry Commission of the National Academy of Sciences, the legislation on standards and on the metric system, the official report in defense of vivisection, plans for the reorganization of the scientific departments under the government, and many similar documents. On scientific education contributions have been made by President Jordan, Professors Bessey, Shaler, Coulter, Carhart, Freer, Gage and others equally competent. Editorial articles and

notes have been prepared, whenever it was thought that the weight of the JOURNAL should be used for the defense and advancement of scientific interests.

Progress of Science.

SCIENCE publishes in every issue articles on the progress of science. Sometimes these are announcements of new advances, but nearly always of a character to make them intelligible and interesting to those having no special knowledge of the subject. More frequently, they are reports of work, the details of which are published elsewhere, or reviews of the general advance in some department of science. It would be impossible to mention, within the limits of this advertisement, all those who have made such contributions. They include men of science from practically every university and institution in America showing scientific activity. There is further given, weekly, a series of notes by the most competent authorities, reviewing important scientific advances. The notes contributed by Professors Brinton, Davis, Bessey, Osborn, Howe, Frost and others are of unusual value to those who wish to keep informed on the progress of science. Each week pages of items of scientific news are published, which alone would make it essential for everyone to read the JOURNAL who wishes to keep informed on current scientific interests and activity.

Scientific Literature.

Scientific books are reviewed weekly in SCIENCE, the most recent information and authoritative estimate of new publications being given. It is probable that no journal in America is able to publish reviews of such weight as those contributed to SCIENCE. While the special journals may give information regarding new publications in a single science, it is necessary for everyone to know something of the more important books in other sciences, and for this purpose SCIENCE is essential. Some notice is also given of the contents of special journals and other smaller contributions which might otherwise escape attention.

Discussion.

The weekly appearance of SCIENCE, the wide fields it covers, and the fact that it is read by practically everyone interested in scientific matters, makes it the best medium for discussion and correspondence. This has been generally recognized and the department usually contains contributions of great interest tending to promote acquaintance and intercourse between men of science. This department alone is of sufficient importance to warrant the continuation and success of the JOURNAL.

The future of SCIENCE.

The past history of SCIENCE is a sufficient guarantee of its future usefulness. Such a JOURNAL is essential to the advance and proper recognition of the scientific work of each country, and in America, where men of science are scattered over a great area, with no single center for personal intercourse, it is peculiarly needful. With the growth of science and scientific institutions in America, SCIENCE will occupy an even more important position than at present. It will continue to set a standard to the popular press in its treatment of scientific topics, to secure that general interest in science so essential to its material support, to enlarge the place of science in education and in life, and to demonstrate and increase the unity of sciences and the common interests of men of science.

SCIENCE is a public institution as much as is a university, a museum, or an academy. It was established at great expense, as a gift to American scientific men. Its editors receive no compensation for their services. The receipts are spent in improving a JOURNAL that is essential to the advancement and proper recognition of science in America. All who are interested in the advancement and diffusion of science can assist the JOURNAL in the following ways:

(1) By subscribing to it. The 2,000 large pages annually published, are worth far more than the cost of the JOURNAL, not only to professional students, but also to physicians, clergymen, lawyers, men of business and others who wish to keep informed on the progress of science.

(2) By giving SCIENCE as a present where it will exert an influence beneficial to the recipient, or to the increase of interest in science. The publishers can supply the names of Young Men's Christian Associations and other libraries anxious to receive SCIENCE, but unable to afford the subscription.

(3) By seeing that SCIENCE is received by all educational institutions, libraries, laboratories, etc, where it would be useful. It is true that the presence of SCIENCE in hundreds of libraries interferes somewhat with individual subscriptions, but it is important that its influence be made as wide as possible. At the same time it is hoped that those who can afford to subscribe to SCIENCE will not depend on a library for the reading of a JOURNAL whose contents are of permanent value.

(4) By purchasing from advertisers in SCIENCE when this can be done to the best advantage, and by seeing that scientific books, instruments, institutions, etc., are advertised in SCIENCE. It is evident that an advertisement in SCIENCE is seen by more scientific men than if inserted in twenty daily papers, and insisting on this fact to publishers, makers of instruments, etc., would help the JOURNAL.

UNIVERSITY OF PENNSYLVANIA,
Department of Physics.
Philadelphia, April 16, 1897.

QUEEN & CO., INC.

Gentlemen:—Your new automatic X Ray Tube which I have been using for the last week or more has certainly proved itself most satisfactory. I have never had the least trouble with the automatic adjusting attachment, the vacuum remaining constant during an exposure of whatever degree desired. I regard the Queen self-regulating attachment as the greatest improvement which has been made in X-Ray tubes since the introduction of the "Focus Tube." Everyone who has done radiographic work knows that the hip joint is perhaps the most difficult part of the human anatomy to produce a good picture of. Until the last week I never have gotten a really good hip with a less exposure than ten or fifteen minutes. The last trials were made with the new tube, one with an exposure of three minutes, and the other with an exposure of one minute. The latter is excellent and the former is the best I have yet seen. I shall take pleasure in sending you a copy of one of these. Congratulating you on the results of your efforts at advancement, I am, very sincerely,
ARTHUR W. GOODSPEED.

Queen Self-Regulating X-Ray Tube

HAS THESE ADVANTAGES OVER ALL OTHER FORMS:

(1.) ADJUSTABLE VACUUM; (2.) AUTOMATIC REGULATION OF VACUUM; (3.) LARGE CURRENT CARRYING CAPACITY; (4.) LONG LIFE.

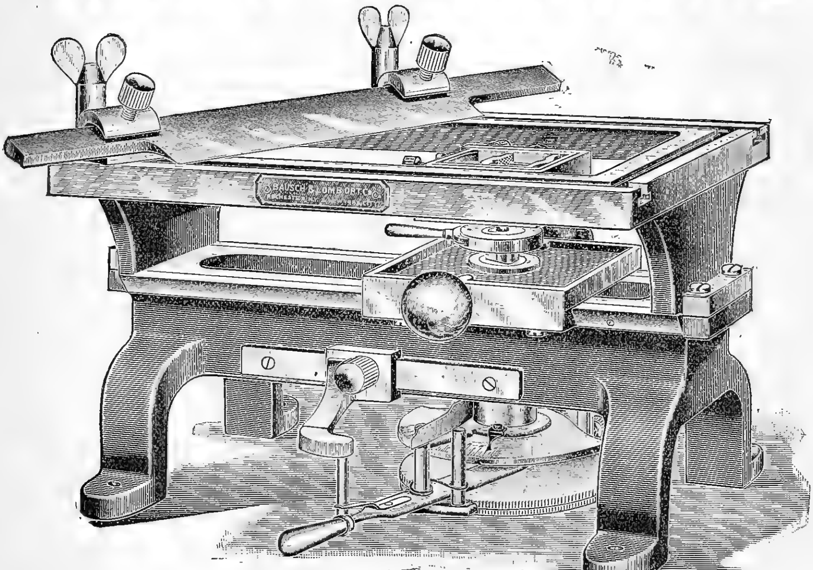
MINOT AUTOMATIC



PRECISION MICROTOME

... FOR ...

PARAFFINE OR CELLOIDINE — SERIAL OR SINGLE SECTIONS

DR. MINOT says (in SCIENCE, Vol. V., p. 862):

"The usual sources of error (in microtomes) are: 1, the bending of the knife; 2, the yielding of the object to be cut; and 3, the jumping of the sliding gear. All these defects are at their maximum in the Rivet type of Microtome of which the best known form is the Heidelberg or Thoma-Jung. It is believed that in the new microtome these three sources of error are materially diminished."

SCIENCE

NEW SERIES.
VOL. VI. NO. 136.

FRIDAY, AUGUST 6, 1897.

SINGLE COPIES, 15 CTS.
ANNUAL SUBSCRIPTION, $5.00.

NEW BOOKS PUBLISHED BY .... **The Macmillan Company**

FOR EVERY BIRD LOVER.

CITIZEN BIRD: A Story of Bird Life.

By **MABEL OSGOOD WRIGHT,** *Author of "Birdcraft," "Tommy-Anne and the Three Hearts," etc.* and **DR. ELLIOTT COUES,** *Author of "Birds of North America," etc., etc.*

FIFTH THOUSAND.
CLOTH. CROWN 8VO.
PRICE, $1.50.

Illustrated with drawings from nature by LOUIS AGASSIZ FUERTES.

A Most Charming Story.

"Lovers of birds have for a long time been on the lookout for the book . . . Now that it has been published it will be eagerly read, and the readers will be pleased to find their highest expectations more than fulfilled. . . . . An unusual feature of the book, one too seldom found in volumes which undertake to combine story and instruction, is the great skill and naturalness with which the two features are mentioned. Here, then, in this book, a volume which cannot be too widely circulated, and which any person, young or old, of the average American intelligence will be glad to read, is a most charming story with people who are characters, not lay figures, who study together the names and habits of over a hundred of our common birds."

From the **Daily Advertiser,** Boston.

A Charmingly Simple, yet fairly complete introduction to Ornithology.

"One naturally turns with high expectations to a new book by two such noted bird lovers, . . . and meets with no disappointment in this case. The book is a charmingly simple, yet fairly complete introduction to the science of ornithology, written for children. . . . There is no other book in existence so well fitted for arousing and directing the interest that all children of any sensibility feel towards birds."

From **The Tribune,** Chicago.

Something unique . . . wholly delightful.

"Something unique in the way of a work on natural history . . . and in this case the result is wholly delightful. 'Citizen Bird' is intended for children and is written in such a bright, cheery, natural manner that there cannot possibly live a child with a soul so dead as not to respond to the charm of its pages. . . . There is such an air of freedom about it, there are so many dramatic touches in it, that one is kept constantly in a state of pleased anticipation."

From **The Evening Post,** Chicago.

A DICTIONARY OF BIRDS.

By ALFRED NEWTON,

Assisted by HANS GADOW, with contributions from RICHARD LYDEKKER, CHARLES S. ROY and ROBERT W. SHUFELDT, M.D. Complete in One Volume with Index and Introduction. Illustrated with a Map and many figures.

Cloth. 8vo. Price, $10 *net*.

The greatest and best book ever written about birds.

"The event more than justifies our prediction that this work would 'prove the most useful single volume ever published on ornithology.' No better balanced treatise of like magnitude exists in the literature of science; there is none in which a standard of excellence set up at the start is more equably maintained to the finish. That standard, moreover, is one hitherto unexampled. Professor Newton has no equal in erudition, so far as the science of ornithology is concerned, and few peers in the art of exposition. His long incumbency of an important chair in the University of Cambridge has made him a masterly teacher, and we have in this Dictionary the most mature fruits of lifelong devotion to his favorite study, set forth with rare skill and tact."

From a review in **The Nation,** by DR. ELLIOTT COUES.

IN PRESS.

WILD NEIGHBORS.

A Book about Animals. By **ERNEST INGERSOLL.** With twenty full-page plates and other drawings made expressly for this book.

A book on the habits, haunts, etc., of certain animals, with some account of the methods of training them in captivity.

IN PRESS.

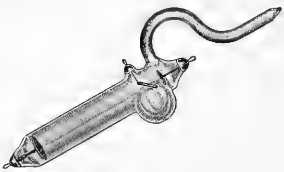
LIFE HISTORIES OF AMERICAN INSECTS.

By Professor **CLARENCE M. WEED,** New Hampshire College of Agriculture and Mechanical Arts.

Chapters on various forms of insect life, most of which are easily obtainable for observation.

THE MACMILLAN COMPANY, 66 Fifth Avenue, New York City.

Scientific Apparatus



"BOWDOIN" X-RAY FOCUS TUBE.

My Specialties Are:

"W-S" X-Ray Apparatus; Weston Ammeters, Voltmeters and Wattmeters; "Chlorid Accumulator" Storage Batteries; Electrical Measuring Instruments; Physical and Optical Apparatus; Pyschological Apparatus, etc.

"Duty Free" Importations from all prominent European makers.

Correspondence requested.

JAMES G. BIDDLE,

Dealer, Manufacturer's Agent and Importer,

909 Drexel Building, PHILADELPHIA.

Dec. 1, 1896. Just Published. Sixth Edition of

THE MICROSCOPE AND MICROSCOPICAL METHODS,

By **SIMON HENRY GAGE**, Professor of Microscopy, Histology and Embryology in Cornell University and the New York State Veterinary College, Ithaca, N. Y., U.S A. Sixth edition, rewritten, greatly enlarged, and illustrated by 165 figures in the text. Price, **$1.50**, postpaid.

COMSTOCK PUBLISHING CO., Ithaca, N. Y.

Cambrian Fossils. A large collection of Upper Mississippi Cambrian fossils from the St. Croix (Potsdam) sandstone for sale. Mostly Trilobites. Send for low prices.

W. A. FINKELNBURG, WINONA, MINN.

NEW CATALOGUE.

We have recently issued a new edition, revised and enlarged to 64 pages, of our catalogue of

Books on Chemistry, Chemical Technology and Physics.

It is arranged by subjects, and includes all the standard books in Chemical and Physical Science, as well as the recent literature up to date.

A copy of this Catalogue will be sent free by mail to any address.

D. Van Nostrand Company,

Publishers and Importers of Scientific Books,

23 Murray St. and 27 Warren St., New York.

Delicious Drink

Horsford's Acid Phosphate

with water and sugar only, makes a delicious, healthful and invigorating drink.

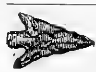
Allays the thirst, aids digestion, and relieves the lassitude so common in midsummer.

Dr. M. H. Henry, New York, says: "When completely tired out by prolonged wakefulness and overwork, it is of the greatest value to me. As a beverage it possesses charms beyond anything I know of in the form of medicine."

Descriptive pamphlet free.

Rumford Chemical Works, Providence, R. I.

Beware of Substitutes and Imitations.



For 12 Cents

I will mail a finely finished original photo, cabinet size, of **Sioux Indian Chief, SITTING BULL, with his Signature.** Have 200 subjects, all different, of leading Western Indians. First-class work. Cabinet Size for 10 cents each. Some sent on selection. Give reference. After seeing sample you will want others. Indian Costume, Ornaments and Weapons. 15,000 Flint Stone Ancient Indian Relics. 100,000 Mineral and Fossil Specimens. Catalogue for stamp. 13th year.

L. W. STILWELL, Deadwood, South Dak.

HOUGH'S "AMERICAN WOODS"

A publication illustrated by *actual specimens*.

WOODS FOR THE STEREOPTICON

Enabling you to show upon the screen characteristic structures projected from nature itself.

WOODS FOR THE MICROSCOPE

Sections 1-1200 in. thick showing three distinct views of grain under each cover glass.

WOOD SPECIMENS FOR CLASS USE

Nothing equals these for use in the class-room.

VIEWS OF TYPICAL TREES

From Nature, photographs and stereopticon views.

WOODEN CROSS-SECTION CARDS

Perfectly adapted to printing (with type or steel plate), painting, India ink work, etc.

If you are interested in wood or trees in any way send for our circulars and sample specimens.

SCIENCE

NEW SERIES.
VOL. VI. NO. 137.

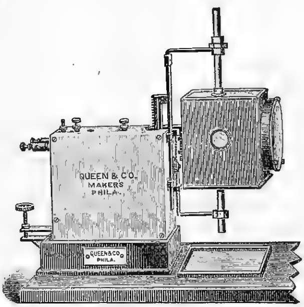
FRIDAY, AUGUST 13, 1897.

SINGLE COPIES, 15 CTS.
ANNUAL SUBSCRIPTION, $5.00.

THE QUEEN PHAROS AUTOMATIC ELECTRIC LAMP.

ITS TWELVE POINTS OF SUPERIORITY:

1. It Keeps in Focus Constantly
2. Regulates and Runs Silently
3. Regulates at Short Intervals
4. The Carbons Separate Very Little . . . .
5. It Lights up the Screen Evenly
6. Maintains the Same Intensity
7. No Attention Required TO HELP it Regulate . . . .



8. Does NOT FLICKER nor Flash . . . .
9. Its Light Power is the Highest . . . .
10. The FULL CRATER is Projected . . . .
11. The Negative Carbon is Non-Luminous . . . .
12. The Adjustments are all Outside . . . .

SPECIALLY DESIGNED FOR PROJECTION IN THE PHYSICAL LABORATORY AND LECTURE ROOM.

ITS mechanism is contained in a nickel-plated case about four and a half inches high, five inches long, two and a quarter inches wide. The carbon holders and gears are placed outside on the narrow front, but the carbons are enclosed in a box with a circular window holding a glass screen to protect the lenses from sparks given off by the arc light.

QUEEN PROJECTION MICROSCOPE. THE MICRO-POLARISCOPE.

STAUROSCOPE with latest improvements, stand unexcelled.

...PROJECTION APPARATUS OF ALL KINDS....

Microscopes, Engineering Instruments, Physical and Chemical Apparatus, Electrical Test Instruments.

SCIENCE

NEW SERIES. VOL. VI. NO. 143. FRIDAY, SEPTEMBER 24, 1897. SINGLE COPIES, 15 CTS. ANNUAL SUBSCRIPTION, $5.00.

The Volcanoes of North America.

By ISRAEL C. RUSSEL,
Professor in the University of Michigan.

Cloth, 8vo. Just Ready. Price, $4.00 *net.*

A work, which taken together with Sir Archibald Geikie's comprehensive volumes on the Ancient Volcanoes of Great Britain, places in the hands of scientists adequate reference works on all branches of this impor tant subject.

Elementary Geology.

By RALPH S. TARR, F. G. S. A.,
Professor of Dynamic Geology and Physical Geography at Cornell University, formerly an Instructor in Harvard University, author of "Economic Geology of the United States," etc.

12mo, cloth. Price, $1.40 *net.*

Intended for High School Use, giving in combination with the "Elementary Physical Geography," by the same author, an excellent foundation for the study of the natural sciences.

An Introduction to Geology.

By WM. B. SCOTT,
Professor of Geology and Palæontology, Princeton University.

12mo, cloth, pp. 570. Price, $1.90 *net.*

An admirable general view of the subject, for those who wish to lay a reliable, fairly proportioned foundation for later specialization, and for those who do not expect to do further work along these lines, yet wish that knowledge of the fundamental principles of the science essential to very good education.

Rocks, Rock-Weathering, and Soils.

By GEORGE P. MERRILL,
Curator of the Department of Geology, United States National Museum, and Professor of Geology in the Corcoran Scientific School and Graduate School of the Columbian University.

Fully Illustrated. 8vo, $4.00 *net.*

Dr. Merrill has taken up a hitherto much neglected line of work, and one which on both economic and scientific grounds is of the greatest interest and importance. He treats of the origin, composition, and structure of the rocks composing the earth's crust, the manner of their weathering, or breaking down, and the causes that lead thereto, and finally of the petrographic nature of the product of this breaking down.

The matter is so arranged that the book will be of value as a work of reference, and also as a text-book for students in the Agricultural Colleges and Experimental Stations, while teachers and students in general geology or physiography will find it to contain much of interest.

The Rural Science Series.

Books which state the underlying principles of agriculture in such language that they may be read at the home firseside, in the office, at the club or grange, or used as text-books. Each is substantially bound in blue cloth.

The Soil:

Its Nature, Relations, and Fundamental Principles of Management.

By F. H. KING,
Professor of Agricultural Physics in the University of Wisconsin.

303 pages, 45 Illustrations. Price, 75 cents.

"I consider it a most desirable addition to our agricultural literature, and a distinct advance over previous treatises on the same subject, not only for popular use, but also for students and specialists, who will find many new and useful suggestions therein."

E. W. HILGARD,
Director of Agricultural Experiment Station,
Berkeley, Cal.

The Fertility of the Land:

A Summary Sketch of the Relationship of Farm-Practice to the Maintaining and Increasing of the Productivity of the Soil.

By I. P. ROBERTS,
Director of the College of Agriculture, Cornell University.

Fully Illustrated. Cloth. Price, $1.25.

This is a companion to Professor King's book, treating the subject from the standpoint of the actual farmer, rather than that of the laboratory. It is the only book which treats the philosophy of farm-practice in a modern way. The book is the result of a long life of teaching, experimenting and farming, and is the most important single book of farming methods which the farmer can secure.

THE MACMILLAN COMPANY, 66 Fifth Avenue, New York City.

Scientific Apparatus

Special Terms for Examination and Introductory Supplies

Elements of Mechanics

INCLUDING

Kinematics, Kinetics and Statics

WITH APPLICATIONS

BY

THOMAS WALLACE WRIGHT, M.A., Ph.D.,

Professor in Union College.

Used last year in the following Institutions among others:

UNIVERSITY OF TENNESSEE, Knoxville, Tenn.
NEW YORK UNIVERSITY, New York.
CUMBERLAND UNIVERSITY, Lebanon, Tenn.
TRINITY COLLEGE, Durham, North Carolina.
WELLESLEY COLLEGE, Wellesley, Mass.
UNIVERSITY OF UTAH, Salt Lake City, Utah.
UNION COLLEGE, Schenectady, New York.
WASHINGTON AND JEFFERSON COLLEGE, Washington, Pa.
OREGON STATE COLLEGE, Corvallis, Oregon.

TESTIMONIALS.

Prof. Ellen Hayes, Wellesley College, Wellesley, Mass., Sept. 14th, 1896

"I am much pleased with it, and have decided to try it in my mechanics class this year."

Prof. D. W. Hering, New York University, University Heights, New York City, Oct. 2nd, 1896

"I am starting a class of about ten or twelve students, and think the book is *easily the best* text-book on the subject for college students of engineering."

Prof. A. H. Buchanan, Cumberland University, Lebanon, Tenn., October 31st, 1896

"It affords me pleasure to testify without solicitation to the superior excellence of this book. More of the fundamental principles of Elementary Mechanics have never been presented in the same scope."

Prof. R. L. H. Correrɾs, Trinity College, Durham, N. C., Sept. 29th, 1896

"I am very much pleased with the book, in fact it is by far the best book on this subject I know of, for a short course. I think the new work far superior to the old one. I like the arrangement much better. I shall continue to use it."

D. VAN NOSTRAND COMPANY, Publishers, 23 MURRAY AND 27 WARREN STS. **New York**

SOCIAL AND ETHICAL INTERPRETATIONS IN MENTAL DEVELOPMENT.

A STUDY IN SOCIAL PSYCHOLOGY.

By JAMES MARK BALDWIN,
Professor in Princeton University, Co-Editor of The Psychological Review.

Work crowned with the Gold Medal of the Royal Academy of Denmark.

12mo. Cloth. Price, $2.60 ***net.***

BY THE SAME AUTHOR.

THE PRINCIPLES OF MENTAL DEVELOPMENT IN THE CHILD AND THE RACE.

METHODS AND PROCESSES.

12mo. Cloth. Price, $2.60 ***net.***

"One's abiding impression of the book is very favorable. Its pages breathe something of the intimacy, the frankness, the personal charm of a clever investigator's note-book." —*The Nation.*

WUNDT'S ETHICS.

AN INVESTIGATION OF THE FACTS AND LAWS OF THE MORAL LIFE.

By WILHELM WUNDT,
Professor of Philosophy in the University of Leipzig.

Translated by JULIA GLOVER, Professor of Philosophy in Rockford College, and EDWARD BRADFORD TITCHENER, Sage Professor of Psychology in the Cornell University. Vol. I.

8vo. Cloth. Price, $2.25 ***net.***

To experts Professor Wundt's works are already familiar in their original language. But there is a public to whom his name is only known as an authority, while his works remain sealed to them; the present excellent translation will, therefore, be appreciated by the latter.

THE CONCEPTION OF GOD.

A PHILOSOPHICAL DISCUSSION.

By JOSIAH ROYCE, Ph.D.,
Harvard University;
JOSEPH LE CONTE, M.D., LL.D., and
G. W. HOWISON, LL.D.,
Professors in the University of California.

A reissue with a new and fuller essay by Professor ROYCE.

Cloth. Crown 8vo. Price, $1.75 ***net.***

CHRISTIANITY AND IDEALISM.

THE CHRISTIAN IDEAL OF LIFE IN ITS RELATIONS TO THE GREEK AND JEWISH IDEALS AND TO MODERN PHILOSOPHY.

By JOHN WATSON, LL.D.,
Professor of Moral Philosophy in Queen's University, Kingston, Canada.

New Edition with Additions.

12mo. Cloth. Price, $1.75 ***net.***

In the present edition of this work, the second part has been enlarged by the addition of three new chapters (eighth, ninth, and tenth) and the intercalation of a dozen pages in the last chapter of the book. The eighth chapter seeks to exhibit the inadequacy of Materialism by showing that the Atomism upon which it rests is inconsistent both with science and with philosophy, and that in its struggle to reach consistency it accomplishes its own euthanasia.

THE SOCIAL TEACHING OF JESUS.

AN ESSAY IN CHRISTIAN SOCIOLOGY.

By SHAILER MATTHEWS,
University of Chicago.

Cloth. Crown 8vo. Price, $1.50.

"The author is scholarly, devout, awake to all modern thought, and yet conservative and pre-eminently sane. His style is fresh, his illustrations illustrate, and for most of his statements he gives Scriptural warrant by the citation of proof texts."—*The Congregationalist.*

PRACTICAL IDEALISM.

By WILLIAM DE WITT HYDE, *President of Bowdoin College, and author of "Outlines of Social Theology."*

Cloth. Crown 8vo. Price, $1.50.

The natural sequence of Dr. Hyde's Theoretical "Outlines," which was pronounced "a peculiarly original, interesting, and suggestive study."—*The Church Standard.*

THE AMERICAN HISTORICAL REVIEW.

J. FRANKLIN JAMESON, *Professor of History in Brown University, Managing Editor.*

Single number, **$1.00.** Annual Subscription, **$3.00.** Issued quarterly. Vols. I. and II., bound in half morocco, **$4.00** *net.*

New Scientific and Philosophical Books.

SOCIAL AND ETHICAL INTERPRETATIONS IN MENTAL DEVELOPMENT.

A STUDY IN SOCIAL PSYCHOLOGY.

By **JAMES MARK BALDWIN,**

Professor in Princeton University, Co-Editor of The Psychological Review.

Work crowned with the Gold Medal of the Royal Academy of Denmark.

12mo. Cloth. Price, $2.60 *net*.

BY THE SAME AUTHOR.

THE PRINCIPLES OF MENTAL DEVELOPMENT IN THE CHILD AND THE RACE.

METHODS AND PROCESSES.

12mo. Cloth. Price, $2.60 *net*.

"One's abiding impression of the book is very favorable. Its pages breathe something of the intimacy, the frankness, the personal charm of a clever investigator's note-book."
—*The Nation.*

WUNDT'S ETHICS.

AN INVESTIGATION OF THE FACTS AND LAWS OF THE MORAL LIFE.

By **WILHELM WUNDT,**

Professor of Philosophy in the University of Leipzig.

Translated by JULIA GLOVER, Professor of Philosophy in Rockford College, and EDWARD BRADFORD TITCHENER, Sage Professor of Psychology in the Cornell University. Vol. I.

8vo. Cloth. Price, $2.25 *net*.

To experts Professor Wundt's works are already familiar in their original language. But there is a public to whom his name is only known as an authority, while his works remain sealed to them; the present excellent translation will, therefore, be appreciated by the latter.

THE CONCEPTION OF GOD.

A PHILOSOPHICAL DISCUSSION.

By **JOSIAH ROYCE, Ph.D.,**
Harvard University;

JOSEPH LE CONTE, M.D., LL.D., and
G. W. HOWISON, LL.D.,
Professors in the University of California.

A reissue with a new and fuller essay by Professor ROYCE.

Cloth. Crown 8vo. Price, $1.75 *net*.

CHRISTIANITY AND IDEALISM.

THE CHRISTIAN IDEAL OF LIFE IN ITS RELATIONS TO THE GREEK AND JEWISH IDEALS AND TO MODERN PHILOSOPHY.

By **JOHN WATSON, LL.D.,**

Professor of Moral Philosophy in Queen's University, Kingston, Canada.

New Edition with Additions.

12mo. Cloth. Price, $1.75 *net*.

In the present edition of this work, the second part has been enlarged by the addition of three new chapters (eighth, ninth, and tenth) and the intercalation of a dozen pages in the last chapter of the book. The eighth chapter seeks to exhibit the inadequacy of Materialism by showing that the Atomism upon which it rests is inconsistent both with science and with philosophy, and that in its struggle to reach consistency it accomplishes its own euthanasia.

THE SOCIAL TEACHING OF JESUS.

AN ESSAY IN CHRISTIAN SOCIOLOGY.

By **SHAILER MATTHEWS,**

University of Chicago.

Cloth. Crown 8vo. Price, $1.50.

"The author is scholarly, devout, awake to all modern thought, and yet conservative and pre-eminently sane. His style is fresh, his illustrations illustrate, and for most of his statements he gives Scriptural warrant by the citation of proof texts."—*The Congregationalist.*

PRACTICAL IDEALISM.

By **WILLIAM DE WITT HYDE,** *President of Bowdoin College, and author of "Outlines of Social Theology."*

Cloth. Crown 8vo. Price, $1.50.

The natural sequence of Dr. Hyde's Theoretical "Outlines," which was pronounced "a peculiarly original, interesting, and suggestive study."—*The Church Standard.*

THE AMERICAN HISTORICAL REVIEW.

J. FRANKLIN JAMESON, *Professor of History in Brown University, Managing Editor.*

Single number, **$1.00.** Annual Subscription, **$3.00.** Issued quarterly. Vols. I. and II., bound in half morocco, **$4.00** *net*.
Send for circular showing the contents of these volumes.

Send in your subscription for the new year, beginning with the October number, to

ROY HOPPING,

MINERAL DEALER,

5 and 7 Dey Street, NEW YORK.

Important Sale of Rare Minerals.

A great opportunity is afforded to universities, museums and collectors, also others, of purchasing by private contract and in its entirety, the large and valuable collection of minerals known as the "Carne Museum of Penzance," Cornwall. This collection has been pronounced by experts to be one of the finest in the United Kingdom. It was commenced in the early part of this century, and has been in possession of members of the family of the founders ever since. The specimens, many thousands in number, are in splendid condition—many being quite unique. For full particulars, address OWNER, care of Street & Co., 30 Cornhill, London.

NEW CATALOGUE.

We have recently issued a new edition, revised and enlarged to 64 pages, of our catalogue of

Books on Chemistry, Chemical Technology and Physics.

It is arranged by subjects, and includes all the standard books in Chemical and Physical Science, as well as the recent literature up to date.

A copy of this Catalogue will be sent free by mail to any address.

Physik. Institut
d. Univers. Würzburg.

Würzburg 29 Oktob. 97.

Herrn Queen & Co. Philadelphia.

Sehr geehrter Herr!

Für die meinem Institut geschenkte X-Strahlen Röhre sage ich Ihnen meinen besten Dank. Dieselbe hat sich bis jetzt sehr gut bewährt, und ich finde das von Ihnen angewendete Princip zur Regulirung des Vacuums besonders sinnreich. Die Bilder würden noch bedeutend schärfer ausfallen, wenn das Platinablech der Kathode vollständig eben und polirt wäre. Ich ersuche Sie mir mitzutheilen zu welchem Preis ich Ihre Röhren erhalten könnte.

Hochachtungsvoll.

Prof. Dr. W.C. Röntgen.

TRANSLATION.

MESSRS. QUEEN & Co., Philadelphia.

GENTLEMEN:

I beg to thank you for the X-ray tube presented to my laboratory. It has worked very satisfactorily, and I find the principle you have applied to the regulation of the vacuum especially ingenious. The images would be even sharper if the platinum plate of the cathode were absolutely plane and polished. Please let me know at what price you can furnish me these tubes.

Yours truly,

PROF. DR. W. C. ROENTGEN.

New Scientific and Philosophical Books.

SOCIAL AND ETHICAL INTERPRETATIONS IN MENTAL DEVELOPMENT.

A STUDY IN SOCIAL PSYCHOLOGY.

By JAMES MARK BALDWIN,

Professor in Princeton University, Co-Editor of The Psychological Review.

Work crowned with the Gold Medal of the Royal Academy of Denmark.

12mo. Cloth. Price, $2.60 *net*.

BY THE SAME AUTHOR.

THE PRINCIPLES OF MENTAL DEVELOPMENT IN THE CHILD AND THE RACE.

METHODS AND PROCESSES.

12mo. Cloth. Price, $2.60 *net*.

"One's abiding impression of the book is very favorable. Its pages breathe something of the intimacy, the frankness, the personal charm of a clever investigator's note-book." —*The Nation.*

WUNDT'S ETHICS.

AN INVESTIGATION OF THE FACTS AND LAWS OF THE MORAL LIFE.

By WILHELM WUNDT,

Professor of Philosophy in the University of Leipzig.

Translated by JULIA GLOVER, Professor of Philosophy in Rockford College, and EDWARD BRADFORD TITCHENER, Sage Professor of Psychology in the Cornell University. Vol. I.

8vo. Cloth. Price, $2.25 *net*.

To experts Professor Wundt's works are already familiar in their original language. But there is a public to whom his name is only known as an authority, while his works remain sealed to them; the present excellent translation will, therefore, be appreciated by the latter.

THE CONCEPTION OF GOD.

A PHILOSOPHICAL DISCUSSION.

By JOSIAH ROYCE, Ph.D.,

Harvard University;

JOSEPH LE CONTE, M.D., LL.D., and G. W. HOWISON, LL.D.,

Professors in the University of California.

A reissue with a new and fuller essay by Professor ROYCE.

Cloth. Crown 8vo. Price, $1.75 *net*.

CHRISTIANITY AND IDEALISM.

THE CHRISTIAN IDEAL OF LIFE IN ITS RELATIONS TO THE GREEK AND JEWISH IDEALS AND TO MODERN PHILOSOPHY.

By JOHN WATSON, LL.D.,

Professor of Moral Philosophy in Queen's University, Kingston, Canada.

New Edition with Additions.

12mo. Cloth. Price, $1.75 *net*.

In the present edition of this work, the second part has been enlarged by the addition of three new chapters (eighth, ninth, and tenth) and the intercalation of a dozen pages in the last chapter of the book. The eighth chapter seeks to exhibit the inadequacy of Materialism by showing that the Atomism upon which it rests is inconsistent both with science and with philosophy, and that in its struggle to reach consistency it accomplishes its own euthanasia.

THE SOCIAL TEACHING OF JESUS.

AN ESSAY IN CHRISTIAN SOCIOLOGY.

By SHAILER MATTHEWS,

University of Chicago.

Cloth. Crown 8vo. Price, $1.50.

"The author is scholarly, devout, awake to all modern thought, and yet conservative and pre-eminently sane. His style is fresh, his illustrations illustrate, and for most of his statements he gives Scriptural warrant by the citation of proof texts."—*The Congregationalist.*

PRACTICAL IDEALISM.

By WILLIAM DE WITT HYDE, *President of Bowdoin College, and author of "Outlines of Social Theology."*

Cloth. Crown 8vo. Price, $1.50.

The natural sequence of Dr. Hyde's Theoretical "Outlines," which was pronounced "a peculiarly original, interesting, and suggestive study."—*The Church Standard.*

THE AMERICAN HISTORICAL REVIEW.

J. FRANKLIN JAMESON, *Professor of History in Brown University, Managing Editor.*

A great opportunity is afforded to universities, museums and collectors, also others, of purchasing by private contract and in its entirety, the large and valuable collection of minerals known as the "Carne Museum of Penzance," Cornwall. This collection has been pronounced by experts to be one of the finest in the United Kingdom. It was commenced in the early part of this century, and has been in possession of members of the family of the founders ever since. The specimens, many thousands in number, are in splendid condition—many being quite unique. For full particulars, address OWNER, care of Street & Co., 30 Cornhill, London.

NEW CATALOGUE.

We have recently issued a new edition, revised and enlarged to 64 pages, of our catalogue of

Books on Chemistry, Chemical Technology and Physics.

It is arranged by subjects, and includes all the standard books in Chemical and Physical Science, as well as the recent literature up to date.

A copy of this Catalogue will be sent free by mail to any address.

COMSTOCK PUBLISHING CO., Ithaca, N. Y.

Exhaustion

orsford's Acid Phosphate.

Overworked men and women, the nervous, weak and debilitated, will find in the Acid Phosphate a most agreeable, grateful and harmless stimulant, giving renewed strength and vigor to the entire system.

Dr. Edwin F. Vose, Portland, Me., says: "I have used it in my own case when suffering from nervous exhaustion, with gratifying results. I have prescribed it for many of the various forms of nervous debility, and it has never failed to do good."

Desciiptive pamphlet free on application to
Rumford Chemical Works, Providence, R. I.
Beware of Substitutes and Imitations.

For sale by all Druggists.
